Identification of group membership is the core cognitive process of group-based cooperation as it results with the differential perception, attitudes, and behaviors toward the members of the different groups. There is a general tendency to prefer and favor one's own group in various psychological domains such as attention, memory, attitudes, empathy, evaluations, social attribution, allocation of resources, or approach-avoidance behavior. Such preferences often occur very fast and are detectable on a neurophysiological level (e.g., Boksem et al. 2012; Bruneau and Saxe 2010; Cheon et al. 2011; Dickter and Bartholow 2007; Enge et al. 2015; Harris and Fiske 2006; Volz et al. 2009). The fact that social categorization affects many different cognitive and affective processes confirms the hypothesis that it constitutes a separate cognitive system, evolved to maintain the complex social relations (Kinzler and Spelke 2007).

Importantly, the tendency to favor cooperation with ingroup members is present in regard to various types of group memberships: racial/ethnic, nationality, age, gender, political affiliation, kinship, sports team fans, etc. It even occurs in the so-called "minimal group" condition, i.e., when group membership is very arbitrary and contextual (Tajfel et al. 1971; Otten 2016), and even in such situations the differences in responses to group membership information can be fast and automatic (Gamond et al. 2017).

Although such preferences for ingroup members can be counterbalanced by other processes such as social hierarchy perception or top-down control, they constitute the basis of

group-based cooperation, largely unconditional and automatic. The ability to make automatic decisions on cooperation can be evolutionarily advantageous because it reduces costs and allows to make multiple choices necessary to interact with many individuals. Recent studies showed that unconditional cooperation largely depends on specific neurohormonal mechanisms. More specifically, a neurohormone oxytocin is supposed to favor cooperating behavior by reducing stress and fostering social bonding and affiliation (Crespi 2016). Initially studied as a mechanism supporting mother-to-child relations, oxytocinergic system was found to be universally stimulating cooperation within various types of meaningful ingroups including kinship, ethnic, and cultural groups (Crespi 2016; De Dreu and Kret 2016). In humans, oxytocin promotes within-group cooperation by increasing empathy toward group members, compliance with group norms, and trust and discriminating against outgroup members (De Dreu and Kret 2016). Studies also confirm that oxytocin promotes intuitive cooperation with ingroup members rather than deliberate, i.e., is a part of unconditional, group-based cooperation (Velden et al. 2017). The question of how oxytocinergic system “chooses” the specific group membership and integrates with the cognitive mechanisms of social categorization, however, remains largely unclear.

Social Cognition in Strategic Cooperation

The second type of cooperation is between unrelated individuals and is not conditioned by group membership. It is a form of strategic behavior, depending on contextual information and expectations of future interactions. This type of cooperation is generally studied using theory of games approach and analyzes cooperative behavior in terms of potential costs and benefits associated with specific strategy. Although the notion of strategic cooperation can be applied to species without a brain, it is generally assumed to be very demanding in terms of partners' cognitive abilities (Brosnan et al. 2010). The need for these abilities results from several specific features

of strategic behavior. Brosnan et al. (2010) point to three factors contributing to the demand for specific cognitive ability needed for strategic cooperation. First, high mobility of partners and increasing number of interactions require good memory and ability to store and retrieve information on past interactions. Second, strategic behavior is often based on time delays between investments and rewards. When such delays take place in interactions, the probability of cheating increases. Individuals have to manage the problem of time delays, both by improving memory for past interactions and by developing skills to correctly anticipate future actions and events. Third, as sustainable strategic cooperation needs positive reinforcement (i.e., agents must receive rewards for their donations to others), temporal delays become a problem for associative learning. To manage this problem, individuals must develop abilities, which make possible behavior oriented toward a delayed reward.

In human societies, individuals are involved in numerous interactions with unrelated others, which don't imply immediate and automatic rewards. The abilities necessary to participate in cooperation with unrelated others are supposed to coevolve with the complexity of social organization itself (Dos Santos and West 2018). The unique human ability to cooperate in large societies with unrelated others and with significant time delays can be explained by reference to either general or specialized cognitive abilities. The general intelligence hypothesis assumes that larger brains allows humans to perform more sophisticated calculations, have better memory, plan for a long-term periods, and perform other cognitive operations more efficiently, whereas the social and cultural intelligence hypotheses state that human societies evolved due to specific needs of their sociality or even “ultra-sociality,” involving living in cultural groups (Hermann et al. 2007).

In accordance with the general intelligence hypothesis, larger brain and more efficient cognitive processing can indeed foster strategic cooperation. Abilities to calculate future outcomes and experience delayed rewards as actual reward and store and

retrieve information about partners and their past actions are universally supporting participation in strategic cooperation (Brosnan et al. 2010).

At the same time, there is strong evidence that humans evolved more specialized social skills necessary to handle strategic cooperation. These skills and abilities include:

- Effective social communications via language and nonverbal means, allowing to rapidly and accurately store and transfer a great amount of detailed information about other individuals, past interactions, and relevant contextual information.
- Fast and accurate recognition of social cues necessary to identify social position of partners and, consequently, to form expectations concerning their possible behavior in interaction.
- Action recognition.
- Fast and accurate recognition of other individuals' mental and emotional states, attitudes, and intentions, necessary to reconstruct their likely strategy and probability of cheating.
- Social signaling, i.e., using self-presentation techniques via control over bodily and facial expressions to demonstrate social status or intentions and to manipulate others' perception.

Studies in cognitive and neuroscience reveal the existence of specialized systems for performing these tasks. For strategic cooperation, correct identification of other's actions and intentions is crucial as it is directly related to decoding others' strategies, including the possibility of cheating, which is the key threat to cooperation. Three integrated neurocognitive systems jointly performing these tasks can be identified: social perception, action recognition, and theory of mind (Yang et al. 2015). The neural system of social perception is especially tuned for face processing and involves regions in the fusiform gyrus (FFG), posterior superior temporal sulcus (pSTS), orbitofrontal cortex (OFC), and amygdala. Action observation involves a mechanism of imitation, which is more self-referral and relies upon the so-called mirror neurons, i.e., neurons similarly

activated both during observation of others' actions and performing these actions by individuals themselves. The mirror neuron system is basically located in pSTS, inferior parietal lobule (IPL), and posterior inferior frontal gyrus (IFG). Theory of mind, i.e., the ability to reconstruct other's mental representations of themselves and their environment, is performed by a neural system typically associated with the temporoparietal junction (TPJ), medial prefrontal cortex (mPFC), and some other regions including pSTS, which was recently proposed to play the core role in integrating these three systems (Yang et al. 2015).

Conclusion

Although cooperative behavior is common among various species and is often regulated by genetic factors, in human societies it largely depends on cognitive abilities. Large size and complexity of social life require cooperation with both related and unrelated others, in a flexible manner and with significant temporal delays between other-benefiting behavior and potential future rewards. Both general-purpose cognitive abilities and more specialized mechanisms of social cognition coevolved with human social organization to maintain complex forms of cooperation.

Unconditional cooperation with related others, typical in nonhuman species and evolved by kin selection, becomes much more sophisticated in humans. The key element of social cognitive abilities underlying such group-based cooperation is social categorization. Ingroup-favoring behavior requires the ability to identify social affiliative relations, and in human societies affiliation involves multitude group memberships, flexible and interacting with each other. To navigate the multiple social categorizations and identities, humans developed advanced neurocognitive machinery, which helps to integrate information on group membership with attention, memory, evaluations, approach-avoidance predispositions, decision-making, and other cognitive processes relevant for cooperation.

Strategic cooperation, based on rational investments and expectations of future rewards, involves a wide set of cognitive mechanisms. Given the complexity of social organization, successful strategic cooperation with individuals outside strong affiliative relations needs both general cognitive abilities (efficient memory and computational resources, ability for long-term planning, and controlling immediate behavioral responses for delayed rewards) and specialized social cognition skills. The latter include social communication and signaling, status recognition, and especially the ability to detect and reconstruct others' internal states and intentions and predict their future behaviors.

All kinds of specific social cognitive processes necessary for cooperation have their neural basis and include both automatic and controlled mechanisms described by the dual-process theories. Although group-based cooperation relies more on automatic processes and strategic behavior more on controlled ones, they are often interacting and mixed. Group-based cooperation is driven by unconditional imperative to benefit ingroup, but due to the complexity of social categorization and individuals' strategic self-interests, it can be counterbalanced by controlled processes. In turn, deliberate cooperation with unrelated others can be downregulated and substituted by more cost-effective automatic responses used as social heuristics. The differences in individuals' social cognitive abilities, contextually available information, as well as other factors, such as culturally determined differences in social perception and normative orientations, produce variety of social situations in which cooperation and cooperative alliances establish, change, and dissolve.

Definition

Cooperation is a helpful act performed by one individual that benefits a second individual of the same species; here we focus on cooperative interactions between two or more individuals belonging to the same species in the mammalian Order Carnivora.

Introduction

Humans show an unprecedented capacity for empathy and prosocial behavior, but understanding the origins and maintenance of cooperation is an evolutionary puzzle. Why do individuals help others at a personal cost to themselves? Anthropologists have made excellent progress in tackling this long-standing question. To reveal the human origins of cooperation, traditional approaches include the study of the fossil record to reconstruct material cultures and tools used by our ancestors. Other workers study the behavioral patterns of living nonhuman primates to uncover the conditions shaping cooperation. In 1969, Schaller and Lowther proposed the novel idea that studying the lives of extant social carnivores might offer new clues about the origins of cooperation in early hominins beyond those available from these traditional approaches. Here, I synthesize the substantial information currently available about the ways social carnivores cooperate and then discuss how these insights inform our understanding of cooperation in mammals, including early hominins.

Cooperation in Social Carnivores

Extent of Cooperation in Mammalian Carnivores

The mammalian Order Carnivora contains ~300 extant species that together are global in distribution, occupying a range of habitats and dietary niches (e.g., herbivores, omnivores, carnivores; Wilson and Reeder 2005). The vast majority of carnivores (~85–90%) are solitary, with conspecifics interacting only to mate or raise young. In contrast, the social carnivores interact regularly with each other, forming social groups or

societies. Although the social carnivores evolved from noncooperative ancestors, individuals within these extant species cooperate with group-mates to hunt large game, defend resources, guard against predators, attack others, and/or rear young (Smith et al. 2012, *In press*). Moreover, older and socially dominant individuals often emerge as leaders in the domains of group movement, food acquisition, within-group conflict mediation, and between-group interactions (Smith et al. 2016).

Because social carnivores are relatively elusive and long-lived, studies spanning one or more decades capture some of the best information about cooperation in social carnivores (Smith et al. *in revision*). Thus, for brevity, I focus on key examples from long-term studies to elucidate the ways this cooperation has coevolved with other traits across Carnivora (Smith et al. 2012). In doing so, I explain the clues that these species of Carnivora offer into understanding cooperation more generally.

Hunting of Large Game

Group life permits individuals in many of the social carnivores to improve their ability to acquire energy-rich prey that vary both spatially and temporarily in the predictability. Spotted hyenas (*Crocuta crocuta*), African lions (*Panthera leo*), African wild dogs (*Lycaon pictus*), and wolves (*Canis* spp.) are among the best-studied of the cooperative hunters. For these species, multiple hunters are often required to secure a single prey animal, each of which represents energy-rich food item that may weigh hundreds of kilograms. Across the Carnivora, additional meat gained from cooperative hunting appears to permit mothers to increase their investment in current reproductive effort by increasing offspring number and also to increase their own body size relative to that of males; cooperatively hunting species often produce more offspring and are less sexually dimorphic than species lacking cooperative hunting (Smith et al. 2012).

Natural selection favors individuals to hunt in optimal group sizes. Whereas spotted hyenas most often hunt alone or in pairs and lions hunt in intermediate groups, wild dogs gain the greatest per capita energy gain when hunting in the large groups (reviewed by Smith et al. 2012). Foragers must balance the benefits of group hunting with the ensuing costs of competition for access to food once prey is obtained. Intense feeding competition often favors groups structured by fission-fusion dynamics in most social carnivores. Individuals regularly break up (fission) from group-mates to hunt on their own or in small subgroups during times of food scarcity but then gather (fusion) into large subgroups to feed when food is abundant.

Coalition Formation and Defense of Resources

Despite their highly cooperative nature, within-group competition regularly occurs among social carnivores over limited resources. Intragroup coalitions form when two or more individuals join forces to direct aggression towards two or more members of their group. Among the carnivores, the patterns of evolutionary forces favoring coalition formation are perhaps best-studied for spotted hyenas living in female-dominated societies. Maternal rank is passed on from mother to offspring. As in many Old World monkeys, individual spotted hyenas learn their social ranks based upon a process of associated learning and repeated maternal interventions during fights (Holekamp et al. 2012). Spotted hyenas also bias their social support towards kin during intragroup disputes but gain direct benefits from reinforcing the status quo by attacking subordinates. Thus, kin selection and direct benefits appear to favor intragroup coalitions via the inclusive (direct + indirect) fitness benefits.

Intergroup coalitions involve multiple group-mates joining forces to direct attacks towards conspecifics belonging to a different social group. This behavior occurs in spotted hyenas, meerkats, and other species of the Carnivora. Interestingly,

although meerkat groups are comprised of closely related group-mates that cooperate in intergroup conflicts, group warfare in spotted hyenas involves kin and nonkin joining forces to attack members of other social groups. As such, spotted hyenas cooperate in group attacks against neighboring group despite their low levels of genetic relatedness with group-mates, presumably gaining direct benefits from their cooperative actions.

Predator Protection

Cooperative defense against predators includes mobbing of predators (e.g., group members collectively fend off potential predators by attacking them) or cooperative vigilance, defined here as any behavioral adjustments that reduces the risk of predation for members of the group. In general, mothers of species that cooperatively defend themselves from predators invest more in current reproduction, weaning offspring at later ages than do mothers of noncooperative species of the Carnivora (Smith et al. 2012). Species living in dense populations are most likely to cooperatively defend themselves from predators, presumably because cooperative defense is mainly a numbers game, requiring a large number of individuals to detect and cooperatively mob predators. Because their small body sizes make them vulnerable to predation, meerkats offer important insights into the evolution of cooperative defense against predators. Sentinels take turns looking out for predators and make alarm call to warn others of threats. Interestingly, meerkats gain both direct and indirect benefits from this behavior, with sentinels typically only assuming this role when they have feed and the costs to the caller are low (reviewed by Smith et al. [in revision](#)).

Alloparenting

Alloparental care is defined here as all aspects of care in which individuals guard, groom,

carry, play with, feed, or nurse the offspring of others (Creel and Creel 1991). As in many nonhuman primates, alloparenting is correlated with an increased brain size relative to body size in carnivores, suggesting that alloparenting enhances energy required to sustain neural tissue across the Carnivora (Smith et al. 2012).

Carnivores may engage in communal care of offspring that are not their own as members of plural or singularly breeding societies. Plural breeders with communal care include Artic foxes (*Alopex lagopus semenovi*), European badgers (*Meles meles*), banded mongooses (*Mungos mungo*), lions, and white-nosed coati (*Nasua narica*; Lukas and Clutton-Brock 2012). Shared communal dens allows for protection against infanticidal male lions (Packer et al. 1990). Similarly, spotted hyenas benefit from group defense of young from predation by lions (Smith et al. 2012). Singularly breeding carnivores in which only one member of a sex typically breeds is seen in many species belonging to the dog and mongoose families. In these groups, reproduction is typically restricted to one breeding pair and alloparenting is provided by nonbreeders, often including allonursing. One of the best-studied mongooses, the meerkat, has one breeding pair that actively evicts subordinate helpers if they attempt to breed (Lukas and Clutton-Brock 2012).

Conclusion

Although the extent to which early hominins ate meat is unclear, this article elucidates the numerous ways beyond group hunting that the social carnivores cooperate, all of which are also relevant to the ways that early hominins likely cooperated. Social carnivores therefore offer new interesting opportunities to study of convergent evolution in cooperation and will likely continue to shed new light on the origins of cooperation in early hominins. Species from both groups cooperatively hunt large game, defend resources, guard

against predators, and rear young. For example, early hominins were themselves likely hunted or otherwise killed by carnivores (reviewed by Smith et al. 2012). The evolution of cooperative defense of food and space, breeding, and protection from predators, as well as fission-fusion dynamics, in the Order Carnivora suggest that this taxonomic group continues to offer underexploited opportunities for testing hypotheses relevant to the evolution of hominins.

Large-scale comparative analysis of extant species of Carnivora indicates that multiple traits coevolved with the ability to cooperate; these correlates include a reduced sexual dimorphism, increased reproductive investment, high population density, fission-fusion dynamics, endurance hunting of big game in open habitats, and large brains (Smith et al. 2012). Similar traits may have also coevolved with cooperation in early hominins. Thus, studying the patterns of cooperation in social carnivores will surely continue to yield new and important insights that will contribute to our understanding of the evolution of cooperation more broadly for years to come.

Cooperation in Social Insects

Raghavendra Gadagkar
Centre for Ecological Sciences,
Indian Institute of Science, Bangalore, India

Many species of insects, such as ants, bees, wasps and termites, organize themselves into societies that parallel, and sometimes better,

human societies. They have impressive levels of social organization, communication, division of labor, cooperation and conflict, altruism and self-sacrifice, policing and punishment, and learning and teaching. They can accomplish feats in warfare with neighboring colonies or feats of internal cooperation such as the construction of sophisticated nests or mounds, which are impossible for individual colony members. They are organized into colonies whose sizes range from a few individuals up to a million or more, occupying from a few centimeters to hundreds of square kilometers (Fig. 1).

Consider a honey bee colony – perhaps the best known insect society (Winston 1987; Seeley 2010; Page 2013). Their colonies comprise tens

of thousands of individual bees, among which there is a single, large, and fertile female bee who is called the queen. Only the queen is mated, and with a store of sperm gathered from many males during her nuptial flight at the beginning of her life, she can lay thousands of eggs per day, both fertilized eggs that develop into females and unfertilized eggs that develop into males. Colonies may comprise a few male bees, also known as drones. The proverbially lazy drones do not take part in social life and do not contribute to domestic work. Instead, they leave their nests of birth and attempt to mate with virgin queens of other colonies. Drones successful in mating die in the act of copulation as their genitals are severed from their bodies and left hanging

Cooperation in Social Insects, Fig. 1 Examples of the major eusocial insects. Upper left, the tropical weaver ant, *Oecophylla smaragdina*; upper right, the Asian dwarf honey bee *Apis florea*; lower left, the best studied Indian

paper wasp *Ropalidia marginata*; lower right, the tropical mound-building termite (*Odontotermes obesus*). (Photos courtesy Dr. Thresiamma Varghese)

onto the females. The rest of the colony comprises smaller nearly sterile female bees, called workers. Workers have lost their genitalia over evolutionary time and cannot mate and cannot produce female offspring. They have small ovaries (much smaller than those of the queen), but these usually remain undeveloped in the queen's presence. Only upon the death of the queen and the colony not being able to rear a new queen do some workers develop their ovaries and lay a few haploid, male-destined eggs. In the presence of a healthy queen, workers refrain from reproduction and spend their whole lives working for the welfare of their colonies. Various tasks required for the functioning of the colony are performed in an orderly, systematic fashion through a process known as age polyethism. Young bees begin by cleaning the nest, after which they successively transition to perform the tasks of building the nest, feeding the larvae, guarding the nest, and finally venturing out to forage for pollen and nectar, which serve as the sources of protein and carbohydrate, respectively, for the growing larvae. The task a bee performs depends on its relative age in the colony. At the age at which they build the nest, they have active wax glands that convert the nectar consumed into wax, which is used for building the nest. As the worker bees get older, these wax glands degenerate, and their hypopharyngeal glands develop instead, secreting, many substances that are added to the diet of the larvae. Such relative age-based polyethism has a built-in flexibility permitting the colony to adaptively respond to unexpected changes in demography. Upon experimental removal of old bees, the relatively older of the intranidal workers becomes precocious foragers, leaving the nest at an abnormally younger absolute age than expected in normal colonies. Conversely, upon experimental removal of young bees, the youngest of the foragers become over-aged nurses, reverting to nursing, regenerating their already atrophied hypopharyngeal glands.

Division of labor is also modulated by the spatial distribution of tasks, and of the bees, and by their relative sensitivities of to the cues signaling the need to perform certain tasks.

Queens mate with several males and produce daughters of several patriline, contributing to the variability in the sensitivities of the bees to perform different tasks. For instance, bees differ in their response thresholds to the smell of dead bees so that undertaker bees are those that are most sensitive to the smell. If a colony is missing the most sensitive patriline, however, the intensity of the smell will soon be adequate for another patriline to remove the dead bees. Sources of pollen and nectar are located by some foragers, acting as scout bees; successful scouts return to the hive and recruit naïve bees to transport the pollen or nectar back to the hive. This they do by the well-known honey bee dance language. When the source is nearby, they perform a round dance motivating the bees to search nearby for the flowers with the expected smell. When the source is more than about 500 m, they perform a waggle dance, communicating specific information about the distance and direction of the food source. Bees estimate the distance and direction of the food source by the image motion on their eyes of the surrounding landscape (optic flow) and a process of dead reckoning called path integration, keeping track of their successive linear and angular displacements as they meander on their outward search flights (Wehner 1992, Mandal 2018). Worker bees thus devote their whole lives to the welfare of their colony and do not reproduce, even in the form of a few male-destined eggs that they can potentially lay. This is an extreme level of cooperation that we label as altruism. Even more impressive is their readiness to sting any marauder of their nest, an act that leads to their immediate death, as they cannot withdraw their stings from the bodies of their victims, owing to its outward-pointing barbs.

While there are some 10 species of honey bees worldwide, all belonging to the genus *Apis*, in the family Apidae, there are at least 15,000 species of ants, all belonging to the family Formicidae, found everywhere except in the Arctic and Antarctic poles. The ants have reached comparable levels of social complexity. Their species diversity permits the ants to embrace many lifestyles (Hölldobler and Wilson 1990).

For instance, leaf-cutting ants practice a sophisticated form of agriculture, cultivating fungi in their gardens and feeding a population of up to a million or more individuals only with the products of their labor – fungal spores. Medium-sized workers go out, locate, cut, and transport leaves back to their nests. These pieces of leaves of carefully chosen species are then ground into a fine paste and spread in the garden by even smaller workers. Fungal mycelia are then “planted” in the garden, and the spores eventually harvested. The fungi cultivated – certain kinds of mushrooms – are not known to exist outside the fungal gardens of the ants. Certain cultivars of the fungi appear to have been selected and passed down across generations of ant colonies and occasionally exchanged between colonies. The ants have elaborate adaptations for manuring their gardens with their feces and for keeping out weeds, with the help of a cocktail of antibiotics produced by bacteria they harbor on their own bodies.

In contrast, weaver ants dwell in nests on trees built by stitching leaves together with silk threads. While hundreds of ants use their combined effort to bend and maneuver leaves in alignment, some of them squeeze well-grown larvae to persuade them to donate some of their silk for the community good. Such donation of silk normally meant for their own pupation is costly to the larvae and constitutes an act of altruism even before the individual becomes an adult. Reminiscent of the lazy drones in honey bees, male ant larvae are less likely to contribute silk for nest building. Weaver ants are voracious predators in the tropical habitats of Africa (*Oecophylla longinoda*) and Asia (*Oecophylla smaragdina*) and build interconnected series of nests across several trees, with a single queen producing all the eggs required to maintain their colony populations.

In even greater contrast, ants of the genus *Diacamma* in Asia have permanently lost their queens. Their relatively small colonies (of a few hundred individuals) consist only of workers, one of whom is mated and functions as a gamergate (mated worker) and lays all the eggs for their colony. All workers are born with a pair of wing buds called gemmae, which appear to be

necessary for the female ants to attract males. The gamergate physically mutilates the gemmae of all eclosing workers and thus prevents them from mating and becoming reproductive. If the gamergate dies, the next worker to eclose retains her gemmae, becomes a gamergate, and mutilates all those who eclose after her. Mutilated workers perform all the tasks such as nest building, brood care, and foraging, required to rear the brood of the gamergate. *Diacamma* genus presents a unique method of reproductive regulation, leading to monogamy, i.e., reproductive monopoly by one egg-laying individual.

All social wasps are paper wasps because they construct their nests not with wax as honey bees do, not with leaves as some ants do, and not with soil as termites do but with paper. They manufacture their own paper by scraping cellulose fibers from plants, adding their own secretions to make a pulp and drying it. All social wasps belong to the family Vespidae. There is a very wide variation in the level of social evolution within the Vespidae. Species belonging to the subfamily Vespinae display advanced sociality resembling the honey bees, while species belonging to the subfamily Stenogastrinae are socially very primitive, bordering on the solitary. The subfamily Polistinae are intermediate and are considered primitively eusocial (see below). Their queens and workers are not morphologically differentiated, and most adults eclose being capable of taking on both queen and worker roles. Polistine wasps have been especially useful in investigating the evolution of social behavior because they display the transition from solitary to social life within the lifetime of individual wasps. New polistine wasp nests may be founded by a single-mated female who can, much like a solitary insect, build and guard her nest, lay eggs, forage, and bring her offspring to adulthood, all by herself. Her daughters from the first brood often stay back as sterile workers and assist her in producing more offspring, making the nest now a social unit. New nests may also be founded by small groups of females, in which case they are social units from the start. Female wasps may function as workers for some time and then transition to a queen status by leaving their

parent nests and starting new single foundress nests and new multiple foundress nests as their queens or may replace the queens of their parental nests. These transitions permit us to study the costs and benefits of solitary as well as social life and understand the ecological forces that mold the evolution of social behavior, despite the cost of non-reproduction (Gadagkar 2001).

Termites represent the fourth main group of insect societies. They are rather different in many ways. First, they do not belong to the insect order Hymenoptera like the ants, bees, and wasps but belong to a different insect order, the Isoptera. Second, unlike the Hymenopteran social insects which are haplodiploid (see below), they are diploid. They have both queens and kings that live together as a monogamous pair. Their workers are also of both sexes. In some species, the immature nymphs serve as workers and never complete their metamorphosis into adults. Workers ingest plant material, digest the cellulose with the help of gut microbiota, and feed the larvae and even the adult soldiers by regurgitating food to them by a process known as trophallaxis (Korb and Thorne 2017).

High levels of cooperation have made the social insects ecologically successful – in some tropical forest habitats, social insects, especially, termites and ants, may constitute three-quarters of the animal biomass. Biologists often use the terms cooperation and altruism interchangeably. In both cases, the reference is to behavior costly for the actor and beneficial to the recipient. As described above, social insects are replete with examples of such costly cooperation. However, their levels of social integration and division of labor vary greatly between different species so that they may be labelled as communal, quasi-social, para-social, semi-social, sub-social, or eusocial (Wilson 1971). The last label, “eusocial,” is considered the pinnacle of the evolution of social complexity. Eusocial species exhibit (i) cooperative brood care, so that individuals routinely care for offspring not their own; (ii) overlap of generations, so that caregivers can be younger than those who receive care;

and (iii) reproductive division of labor, so that only one or a few individuals in the colony reproduce, called queens or kings as the case may be, while the rest function as sterile helpers, often called workers. Among the eusocial species, it is customary to recognize two further sub-divisions, namely, the primitively eusocial and the advanced or highly eusocial. Until the 1970s, eusociality was thought to be restricted to ants, bees, and wasps in the insect order Hymenoptera and termites in the order Isoptera. In the last few decades, eusociality has also been discovered in thrips in the order Thysanoptera, aphids in the order Hemiptera, ambrosia beetles in the order Coleoptera, and shrimps, in the arthropod class Crustacea. Barring the case of the naked mole rat that lives in underground tunnels in Africa which curiously fits the definition, eusociality is restricted to insects and some shrimps. Despite this taxonomic range expansion of eusociality, advanced eusociality is restricted to ants, bees, wasps, and termites (Hölldobler and Wilson 1990; Gadagkar 2001; Rubenstein and Abbot 2017).

Biologists ask two kinds of questions about biological traits, the so-called proximate questions (sometimes called “how” questions) and ultimate questions (sometimes called “why” questions). In the context of cooperation in social insects, examples of the proximate kind include questions such as how do social insects recognize nestmates versus non-nestmates and maintain colony integrity; how do they divide colony labor among themselves; how does each member of the colony know what work to do when, and what not to do, so that they can function as an effective group; and how do they accomplish complex group tasks such as building elaborate nests, of locating, bringing, and processing food; etc. There is one overarching ultimate question, namely, how does natural selection favor the evolution of altruistic sterility by a process that is supposed to bring about survival of the fittest (fitness being usually measured as the number of offspring)? This can be split up into several sub-questions such as why does natural selection favor group living instead of

solitary living; why is the division of labor, the partitioning of tasks between different individuals, more efficient than each individual performing tasks independent of each other; and how does natural selection produce elaborate communications systems such as the dance language of honey bees, for example? (Gadagkar 1997).

We now have a fairly sophisticated understanding of the proximate mechanisms of social behavior and cooperation. These mechanisms may vary between the primitively and highly eusocial species. In primitively eusocial species, queens and workers are not morphologically differentiated. Queens and workers and sometimes even the sub-groups of workers that specialize in performing different tasks are referred to as castes. Caste differentiation in the highly eusocial species takes place in their early larval stages leading to the eclosion of differentiated adults that can no longer change their fate. In the primitively eusocial species, however, adults at eclosion are completely or nearly totipotent and can subsequently differentiate into queens or workers. Since the main difference between queens and workers is that of reproduction versus sterility, caste differentiation in highly eusocial species is developmentally regulated, while in primitively eusocial species, it is socially regulated. In highly eusocial species, the starting point of such differentiation is differential nutrition between queen-destined larvae and worker-destined larvae. The difference in nutrition may be one of the quality of the food, as in the case of the honey bee where queen larvae are fed with a sugar-rich royal jelly, while workers' larvae are fed with ordinary worker jelly. Or it may involve a difference in the quantity of food such that better-fed larvae become queens and poorly fed larvae become workers. Either way, differential nutrition channels larvae into alternate developmental pathways such that better-nourished larvae produce more insulin-like peptides, turn on vitellogenin synthesis, develop their ovaries, and become queens. Conversely, poorly nourished individuals produce less insulin-like peptides, produce little or no

Cooperation in Social Insects, Fig. 2 Our current understanding of the proximate mechanism of reproductive caste differentiation

vitellogenin, fail to develop their ovaries, and become sterile workers (Chandra et al. 2018) (Fig. 2). Further subdivision of workers into sub-castes can also be mediated by differential nutrition. In primitively eusocial species where caste differentiation is socially regulated, behavioral dominance-subordinate interactions modulate caste differentiation such that behaviorally dominant individuals become egg-laying queens and subordinate individuals become non-egg-laying workers. Further subdivision among workers into intranidal workers (those who work inside the nest) versus extranidal workers (those who work outside the nest) can also be mediated by similar aggressive interactions such that the relatively more dominant individuals among the workers, work at home, and the least dominant

Box 1 Hamilton's Rule

$$b \cdot r > c \quad \text{or} \quad b/c > 1/r$$

b = benefit to the recipient

c = cost to the altruist

r = genetic relatedness between the recipient and the altruist

or

$$n_i r_i > n_o r_o$$

n_i = number of relatives reared

r_i = relatedness to relatives

n_o = number of offspring reared

r_o = relatedness to offspring

Hamilton's rule defines the condition for the evolution of altruism. The upper forms of the inequality are useful to predict when an individual will be selected to sacrifice itself to help others. The lower form is useful to predict when a sterile individual who rears relatives will be selected over a fertile individual who rears its own offspring

individuals work outside, foraging for food and building material required by the colony.

Social insects accomplish many rather complex tasks both inside and outside their nests that appear to be inconsistent with their small brains and limited neural capacity. The secret of

their success in achieving complex outcomes incommensurate with the cognitive capacities of individual insects is that they use a process of decentralized self-organization – large numbers of individuals follow simple local rules, but there emerges a complex outcome due to their

collective behavior. This is sometimes called social intelligence and is the subject of intense investigations by interdisciplinary teams of biologists, physicists, and mathematicians (Camazine et al. 2003).

Understanding the ultimate causation of sociality, namely, the evolution by natural selection of cooperation and altruism, has been an even greater preoccupation of social insect researchers. The paradox of altruism referred to above was largely solved, at least in theory, by the realization that evolutionary fitness can be gained not only by producing one's own offspring but also by aiding the reproduction of genetic relatives. Indeed, one can combine the two kinds of fitness, direct (through offspring production) and indirect (through aiding genetic relatives), in a simple additive manner. The sum of these two kinds of fitness is known as inclusive fitness. Hamilton's rule predicts that natural selection can promote the evolution of altruistic behavior when the benefit to the recipient of altruism multiplied by the proportion of genes shared between the altruist and the recipient is greater than the cost incurred by the altruist (Box 1). This formulation of the solution to the paradox of altruism is known by several names – inclusive fitness theory, Hamilton's rule, or kin selection. There has been a great deal of effort to develop a sound mathematical foundation of this theory and some (but not enough) effort to see if animals actually behave as if they obey Hamilton's rule. Hamilton's rule can guide empirical researchers in the field and in the laboratory to ask the right questions and measure the right quantities. Nevertheless, very few studies have adequately measured all three parameters in Hamilton's rule to pronounce a clear verdict on whether altruists always obey Hamilton's rule or whether they sometimes get away without obeying the rule. The latter possibility suggests that there may be other ways of solving the altruism paradox. Selection at the level of the individual and also at the level of the whole colony (known as multilevel selection) is sometimes considered as promising avenues

for future research (Gadau and Fewell 2009). Meanwhile, the very validity of the inclusive fitness approach is being questioned by some prominent researchers, leading to a bitter controversy (Nowak et al. 2010). As a result, the study of cooperation in insect societies has gained a new vibrant dynamism, attracting much interest from theoreticians and empiricists alike, well beyond the traditional social insect community. Although many interesting phenomena have been discovered and their evolutionary logic is being worked out, many more phenomena surely await discovery. The study of cooperation in social insects is worthy of attention from practitioners of diverse disciplines, not only physics, chemistry, mathematics, and engineering in the natural sciences but also psychology, sociology, political science, and related disciplines in the social sciences.

Cooperation to Solve the Prisoner's Dilemma

► Evolution of Cooperation

Cooperation Varies with Genetic Relatedness

Max Burton-Chellew
University of Oxford, Oxford, UK

Synonyms

[Altruism](#); [Assortment](#); [Inclusive fitness](#); [Kin discrimination](#); [Kin recognition](#); [Kin selection](#)

Definition

A prediction from Hamilton's rule that altruism is more likely the more related the beneficiary is to the actor/donor. Here we briefly discuss the theoretical reasoning and focus on the empirical support for this prediction in humans.

Introduction

In the most general sense, cooperation occurs when one individual helps another. In evolutionary terms, helping means increasing the lifetime reproductive success of another individual. Genes are selected to produce behaviors that tend to increase their frequency in the population. They can do this via two routes, by inducing behaviors that increase either the reproductive success of their bearer (direct fitness), or the reproductive success of other individuals that tend to carry the same gene (indirect fitness). Hamilton realized this and that therefore natural selection, operating on genes, will lead to individuals that appear designed to maximize the sum of their direct and indirect fitness. Consequently, helping behaviors can evolve when helpers receive personal benefits in return that surpass their initial costs (increasing their direct fitness), e.g., through exchanging favors (reciprocity). Helping behaviors can also evolve even if helpers never receive any benefits, providing they direct their help toward other individuals that tend to carry the same helping gene (altruism, increasing indirect fitness). The easiest way to help individuals that tend to carry the same helping gene is to help close genealogical relatives, and therefore kin can be selected to cooperate altruistically (Kurzban et al. 2015).

Whether a helping behavior between kin will be favored by natural selection depends on three things: the costs to the actor/donor (in terms of reduced lifetime reproductive success), the benefits to the recipient (in terms of increased), and the probability that the recipient carries the same helping gene. In evolutionary terms, the probability that the recipient carries the same gene for helping at the same locus is termed Relatedness. Relatedness is a statistical coefficient genetic describing the similarity between the actor and recipient, relative to the rest of the population (see entry for 'R = Coefficient of Relatedness').

The relationship between these three terms is defined by Hamilton's rule, where $C < Rb$,

which means the benefits have to be greater than the costs, even when discounted by relatedness. Therefore, the more related the recipient is, the more costly the helping behavior can be and still be favored. Hamilton's rule leads to the prediction that cooperation will occur more often between closer relatives than distant relatives. Studies of how human cooperation varies with relatedness typically, for convenience, estimate relatedness on a scale from 0 to 1 by calculating the coefficient of relationship between two individuals, e.g., siblings are related by 0.5. Not that this estimate does not incorporate factors such as inbreeding (see entry for 'R = Coefficient of Relatedness').

Empirical Challenges

Although Hamilton's rule is supported in non-human studies, ethical considerations make it difficult to test experimentally in humans. Therefore human studies are often observational or survey based, and/or typically concern low-cost behaviors. This can be problematic because low-cost behaviors can be under less natural selection pressure, can be favored toward close and distant kin, and can be favored between nonkin for direct benefits (e.g., reputation). Strong tests of Hamilton's rule compare how cooperation varies with the degree of relatedness. Weaker tests only ask if humans cooperate more with kin than nonkin. Although how much people should discriminate between close and distant kin will depend on the costs and benefits and the cues of relatedness available. Note that studies which only measure cooperation toward nonrelatives do not invalidate Hamilton's rule, because they are unable to test the relative importance of Hamilton's rule. Indirect support comes from studies that show a psychological mechanism for recognizing kin, although this mechanism can also result from incest avoidance (Lieberman et al. 2007).

Survey Data

Survey responses, either on line or in the laboratory, often show that individuals expect to be more cooperative toward closer kin (Burnstein et al. 1994; Korchmaros and Kenny 2001; Stewart-Williams 2007), or expect to receive more cooperation from closer kin (Burton-Chellew and Dunbar 2015). For instance they report that they are more likely to donate a kidney to closer kin, although the effect sizes are modest (Stewart-Williams 2007). Burton-Chellew and Dunbar (2015) showed that individuals reported they *expected to receive* more help from closer kin than distant kin in times of crisis. While people still respond that they would help nonrelatives, mostly best friends, the key finding is that cooperation is increased toward close kin in support of evolutionary theory. Complementary data comes from studies that investigate the proximate, psychological, mechanisms governing these behaviors, and they typically show that feelings of "emotional closeness" are an important mediator of helping behaviors (Korchmaros and Kenny 2001).

Observational Data

Survey data has its limitations because the costs may never be realized. An analysis of real helping behaviors came from Smith et al. (1987) who analyzed patterns of giving by relatedness in 1000 wills. They found that when individuals made their wills, they allocated a greater proportion to their closer relatives. Specifically they gave 46% to close relatives ($r = 0.5$), and just 8% when $r = 0.25$ and 1% when $r = 0.125$. However as these transfers occur after death it could be argued they are noncostly. Another prominent nonexperimental study on real costs in real time was by Bowles and Posel (2005). They analyzed how much money male migrant workers sent "home" (remittances) and how this varied with the relatedness of the recipient to the migrant worker. Overall, they found that including relatedness in the model improved the model's accuracy to predict the value of

remittances, although other factors were important too. Likewise, many observational studies tend to find mixed support for the role of relatedness and other factors such as reciprocity in explaining human cooperation, but as explained above, cooperation can be explained by both direct and indirect benefits. The key prediction is that because indirect benefits vary with degree of relatedness, cooperation is greater or more likely with closer relatives.

Experimental Data

Perhaps the first experimental test of how cooperation varies with relatedness in humans was by Madsen et al. (2007). Across three crosscultural studies, participants were asked to adopt a painful posture (an isometric skiing exercise) in exchange for monetary benefits that went to their various relatives. Control treatments included benefits that went to themselves, nonrelatives, and charities. The posture involved supporting one's weight in a way that worked the thigh muscles and rapidly became intensely painful (after ~60 s). The pain may signal muscle damage and thus may indicate a genuine cost in evolutionary terms. A willingness to endure pain on behalf of relatives may also translate into a willingness to pay genuine costs. The longer the participant maintained the posture (cooperated), the more money their relatives got. The results were generally supportive. Cooperation did vary positively with relatedness, although in one study this arguably required including the control measure of help toward oneself, where relatedness = 1, and there were potential sex differences.

Other Factors

Finally, the indirect benefits of helping relatives also depend on other factors that ideally need to be controlled for. First, the indirect benefits of helping a recipient will be greater when they stand to gain more. This will occur when they have a

higher probability of future reproduction (more reproductive value), i.e., generally when they are younger, because the help is more likely to lead to increased reproduction. In both the studies of Madsen et al. and Smith et al., the results were more in line with theory once the reproductive value of the recipients was controlled for (Madsen et al. 2007; Smith et al. 1987). Second, competition occurs at different scales in populations, and relatives often have to compete, decreasing the benefits of kin-directed altruism. This is because helping one relative merely helps them to out-compete another relative, reducing the net gain (Borgerhoff Mulder 2007).

Conclusion

Studies generally find that very costly cooperation is greater toward kin than nonkin, which provides a weak test of Hamilton's rule. More studies are needed that directly test if and how individuals differentiate between close and distant kin.

Group living with allopaparental care

Introduction

Cooperative breeding is characterized by a combination of group living and allopaparental care, i.e., the care of others' offspring. Typically, young of previous broods remain in their natal territory and help raising subsequent offspring of dominant breeders. Hence, the characteristic of cooperative breeding is the joint occurrence of delayed dispersal of young with a propensity to help caring for offspring they have not produced. Such "helpers" may or may not participate in reproduction, but if they do, the majority of young is still produced by more dominant group members. In other words, the "reproductive skew" within groups is usually high.

There are numerous variations of this general pattern, which differs also systematically between taxonomic groups. In birds and mammals, for example, there are two prevailing patterns: either young that delay dispersal from their natal territory help raising their later born siblings, or several females produce offspring jointly and raise them cooperatively, which is usually referred to as "communal breeding" (Koenig and Dickinson 2016). In fishes, insects, and spiders, there are sometimes different variations of these patterns.

For instance, in fishes young delaying dispersal may help raising offspring of unrelated breeders that have replaced their own parents, or they may join forces to raise a brood that has been sired by several different males (Taborsky 1994). In some insects, several females jointly found a nest, in which only the dominant takes over the reproductive role, while subordinates help raising the latter's offspring irrespective of their degree of relatedness to them (Field and Leadbeater 2016). In social spiders, allofeeding of offspring that were not produced by the helpers may reach extreme levels, where helpers are consumed by these young even if they are unrelated to them (Lubin and Bilde 2007).

From an evolutionary perspective, cooperative breeding is of fundamental interest because it involves alloparental care, i.e., apparently altruistic behavior. This provides exceptional opportunities to ask under which circumstances selection will favor individuals accepting an apparent fitness cost at a benefit to the recipients of their helpful behavior.

Evolution of Cooperation

There are two principle ways how such behavior can evolve (Taborsky et al. 2016). Firstly, cooperative behavior may be mutualistic, i.e., the act itself has immediate fitness benefits to the actor; in this case, the behavior will be selected regardless of its beneficial effects on potential receivers. Secondly, cooperative behavior may be altruistic, which means that one individual helps another at immediate fitness costs exceeding the immediate fitness benefits of the act, i.e., the act bears immediate net costs. There are four possibilities how altruism, that is, cooperative behavior bearing immediate fitness costs, can be selected for.

- (1) Kin selection. If the donor and the beneficiaries of the helpful act share a common genealogy, i.e., if they are related by common descent, genetic predispositions for helpful behavior may be favored if the fitness benefits

to the receiver times the degree of relatedness between donor and receiver surpass the fitness costs to the donor. This algorithm has been termed "Hamilton's rule" after its originator William Hamilton (1964).

- (2) Green beard effects. If there is a genetic correlation between cooperative behavior and traits allowing individuals to identify carriers of such genetic cooperation predisposition, co-operators can exercise selective altruism towards other co-operators. Identifier traits can be arbitrary like a green beard, which is the reason why this potential mechanism has been coined "green-beard effect" by its originator (Richard Dawkins 1976).
- (3) Reciprocity. Altruistic behavior may be positively selected if it increases the chance of the actor to get something back in the future that overcompensates the immediate net costs of the act (Trivers 1971).
- (4) Coercion. Prospective receivers may enforce cooperative behavior on potential donors against the latter's fitness interests. As in this case the cooperative behavior reduces the lifetime fitness of donors, countermeasures against such exploitation will be selected. This can lead to an evolutionary arms race just like in brood parasite – host interactions.

Regarding the evolution of cooperative breeding, there is evidence for a role of both mutualism and altruism, and regarding the latter possibility, kin selection and reciprocity seem to be the most important underlying mechanisms (Taborsky et al. 2016).

Why Delay Dispersal?

There are two major ecological constraints that may select for delayed dispersal of offspring, i.e., for a prolonged stay in the natal territory.

- (1) Habitat saturation, which occurs when all areas suitable for breeding are already occupied by superior competitors. This constraint has been implied to explain cooperative breeding in many

bird species (Koenig and Dickinson 2016). (2) High risk, which may prevent dispersal if either the dispersal itself or the subsequent settlement entail exceptionally high risk. This ecological constraint has been identified in cooperatively breeding fishes (Heg et al. 2004).

Why Help?

Staying in the natal territory will usually lead to some form of family formation, but this does not compel individuals to help raising the dominants' offspring. As alloparental care usually entails fitness costs, there must be some benefits compensating for such seemingly altruistic behavior. As has been outlined above, there are in principle two evolutionary mechanisms responsible for costly helpful behavior shown by subordinate group members. (1) They may be related to the beneficiaries, i.e., to the dominant breeders and their offspring. (2) Alternatively, there may be reciprocal benefits to dominants and subordinates, i.e., some sort of trading of commodities between the different types of group members. In Lake Tanganyika cichlids, for instance, it has been shown that the brood care helpers benefit from being protected in the territory of dominants, and in turn they help caring for the latter's brood; in other words, they "pay-to-stay" in a safe territory. The amount of "rent" to be paid by subordinates depends on the need for help and on the demands of dominants, which are communicated to their helpers by restrained aggressive behaviors (Taborsky 2016).

Proximate Mechanisms

Important prerequisites for a proper operation of group living and cooperation in highly social species is the ability of individuals to recognize conspecifics by their group affiliation, rank, role, and/or relatedness. In some cooperative breeders, individuals specialize in different

duties. This is most prominent in animals continuing to grow after maturation such as fish, because this results in body size variation between group members; small and large individuals can perform diverse duties with different efficiencies, for instance direct brood care, digging out burrows, or territory defense. Such behavioral specialization of group members is most highly developed in eusocial insects, but it sometimes occurs also in cooperatively breeding vertebrates where individuals maintain their reproductive potential such as mole rats and cichlids (Taborsky 2016).

Most importantly, relatives should be distinguished from nonrelatives, because this allows differential allocation of altruistic help towards related beneficiaries. Such distinction has been shown to exist in several species of mammals, birds, and fish. While the cooperation propensity rises with increasing relatedness in many mammals and birds, there are cases where this does not hold. In vampire bats, for example, a blood meal is often donated to related young, but most blood donations depend on reciprocal exchanges and not on relatedness. In cooperatively breeding cichlids, relatedness even reduces the helpers' propensity to care for the eggs of dominants, as the latter demand more help from unrelated subordinates. If the alternative "outside options" of subordinates are bad, for instance, because of a high mortality risk outside of a territory, the helpers are prepared to pay a high price for protection and resource use in the dominants' safe territory (Taborsky 2016).

Some studies have shown that individuals may differ consistently in their propensity to cooperate, i.e., they show "helping personalities" which are heritable and hence subject to natural selection. Dominants may respond to such personality differences of subordinate group members.

The hormonal, genetic, and epigenetic mechanisms underlying behavioral decisions of dominant and subordinate group members are hitherto little understood. As many behavioral and physiological traits of several different individuals are involved, this topic features considerable

complexity, which makes it both challenging and rewarding to unravel these mechanisms. As the underlying neurophysiological and endocrine mechanisms seem to be deeply conserved among vertebrates, this allows to study general regulatory mechanisms in cooperative breeders that can be investigated under standardized experimental conditions, like cooperatively breeding cichlids (Taborsky and Taborsky 2015).

Conclusion

Cooperative breeding reflects the most complex form of social organization known among animals, featuring the highest degrees of cooperation and altruism. This applies particularly to its most extreme manifestation, eusocial organization, where individuals forego own reproduction for their entire lives to raise offspring of close relatives. The evolution of such altruism is explained through the action of kin selection or green-beard effects, as the genetic causes for lifelong reproductive abstinence can only be transmitted between generations by the offspring of individuals sharing the same genetic makeup with above average probability. In cooperative breeders that do not cross the line to complete celibacy, which is a social organization occurring in many different taxa, some form of reciprocity may also be responsible for cooperation and sharing of tasks among group members. This makes cooperative breeders a particularly useful target for studies of ultimate and proximate mechanisms of cooperation and social evolution.

By-product mutualism

Definition

The process through which two or more individuals benefit from working together to obtain food resources.

Introduction

Many species benefit from working together, in some form, for the purpose of locating and consuming food. Animals, from insects like the honeybee (*Apis* spp.) to carnivores such as the gray wolf (*Canis lupus*) and orca (*Orcinus orca*), benefit from not only foraging socially but cooperatively. This cooperation has been suggested to be one of the key drivers of evolution, sparking unique cognitive abilities (Wilson 2000).

Cooperative foraging, or by-product mutualism (Connor 1986), distinguishes itself from other social foraging styles (e.g., imitative foraging) in that it occurs when individuals are able to distinguish between group members and engage in altruistic self-restraint and complex communication. These abilities allow group members to coordinate behaviors to achieve a common goal,

thus increasing individual foraging efficiency (Wilson 2000).

Mechanisms Driving the Evolution of Cooperative Foraging

There are five mechanisms for the evolution of cooperative behavior: (1) kin selection, (2) direct reciprocity, (3) indirect reciprocity, (4) network reciprocity, and (5) group selection (Nowak 2006).

Kin Selection

According to Hamilton's rule, evolution favors cooperation when the donor and recipient of a behavior are genetically related to one another. In essence, when two individuals are related, they each benefit from the other's success through their shared genes. Therefore, cooperative behavior among relatives is an investment in one's own genes and is motivated by the individual's drive to promote its own genetic success (Hamilton 1964). Hence, most eusocial groups consist of closely related individuals (Boyd and Richerson 1989).

Direct Reciprocity

Despite the fact that individuals may be more likely to invest resources in a relative, individuals of various species also cooperate with nonrelated individuals, through direct reciprocity. Direct reciprocity results form a tit-for-tat strategy of cooperation between individuals. That is, if *Individual A* shares food with *Individual B* today, then *Individual B* will reciprocate tomorrow. Through this cooperative strategy, the two animals benefit over the long-term despite short-term losses in resources, thus increasing both individuals' overall fitness regardless of relatedness (Nowak 2006).

Indirect Reciprocity

For this strategy, the donor assists a recipient for no immediate direct gain in resources. Instead, in indirect reciprocity, *Individual A* assists *Individual B* who in turn assists *Individual C*, and so on, until another individual assists *Individual A* thus

returning the original investment. Humans are the only species to fully engage in indirect reciprocity likely because of the strong cognitive demands of such a strategy (Boyd and Richerson 1989). This strategy requires that individuals can remember their own actions, the actions of others, monitor group social structures, and the use of language to spread knowledge regarding the actions of others (Nowak 2006). For example, when an individual donates resources (e.g., food or money) to an individual in need, human social groups often hold the donor in high esteem. Indirect reciprocity may even be institutionalized in some societies, in the form of tax deductions for donating to charity. Indirect reciprocity promotes cooperation only when the probability of knowing an individual's reputation exceeds the cost-benefit ratio of the behavior in question.

Network Reciprocity

In a mixed group, where cooperators (individuals who suffer an intentional loss for the purpose of another's gain) and noncooperators (individuals who neither receive a loss nor benefit others) are combined, cooperators benefit their neighbors while noncooperators do not – thus enhancing the fitness of noncooperators while detracting from that of cooperators. To combat this phenomenon, cooperators come together to form a network cluster, excluding noncooperators, within which they can benefit one another. In humans, network reciprocity has been documented in cases when each individual within the network cluster both reports giving and receiving assistance from others within the cluster (Nolin 2012).

Group Selection

Because a group of cooperators has a higher rate of fitness than a group of noncooperators, it is likely that cooperators would reproduce at a higher rate. Thus, cooperators are likely to produce more offspring than do noncooperators, over time eliminating or reducing noncooperators through genetic sampling (Nowak 2006).

The Evolutionary Benefits of Cooperative Foraging

When a group consists purely of cooperators, the members of the group benefit from higher per capita fitness. Alternately, when a group consists entirely of noncooperators, the group members experience lower levels of fitness. However, in a mixed group (consisting of both cooperators and noncooperators), noncooperators experience increased fitness at the cost of the cooperators. Therefore, evolution strongly favors cooperation, but also rewards noncooperators, in the right environment (Nowak 2006).

The proposed causes of the increased rates of fitness, experienced by cooperative groups, include (1) increased vigilance and protection from danger, (2) increased information regarding the location of food sources, (3) increased ability to capture prey, (4) increased efficacy in defending resources, and (5) increased ability to exploit depletable resources (Clark and Mangel 1986).

Increased Vigilance and Protection from Danger

As group size increases, individual bouts of vigilance decrease proportionately. This phenomenon is described as the *group size effect* and results from the premise that as group size increases overall vigilance increases – thus reducing the vigilance required of each individual (known as the *many eyes hypothesis*), allowing individuals to devote more time to obtaining food (Lima 1995).

Increased Information Regarding the Location of Food Sources

Cooperative species benefit from the knowledge of the most experienced group members through imitation, observational learning, or communication. This allows group members to increase the efficiency with which they adapt to novel situations, systematically exploit resources. This is especially true when food resources are located in patches (Kurland and Beckerman 1985; Wilson 2000).

Increased Ability to Capture Prey

Through group cooperation, predators are able to maximize foraging efficiency by taking prey in either greater numbers or of a larger size than they would otherwise be capable of killing if hunting alone. Cooperative hunting requires that individuals are capable of coordinated behaviors. For example, African lions (*Panthera leo*), gray wolves, and orcas have demonstrated increased foraging efficiency through the coordination of movements to herd and contain prey animals by joining forces in order to overpower and kill large prey animals (Wilson 2000).

Increased Efficacy in Defending Resources

As individuals are working to obtain resources as a group, each individual has a similar investment in defending access to food resources against competitors. Thus, individuals benefit from an increased likelihood of maintaining access. For example, gray wolves in Yellowstone National Park actively guard a kill after group members have become satiated (e.g., Mech 1970).

Increased Ability to Obtain Depletable Resources

Cooperative foraging is most beneficial when food resources are unpredictable or scarce, as cooperative groups are likely to locate and exploit resources with greater efficiency than individuals (Wilson 2000). Solitary human foragers living on the savanna, for example, would have expended considerable energy attempting to procure patchily disperse food resources. Alternately, searching together, a group of people are much more efficient at locating and harvesting these resources. Therefore, selection favors those who cooperate with others in these environments (Kurland and Beckerman 1985).

Horn's Principle of Group Foraging

Some species, particularly flocking birds, may benefit from forming a cooperative group under certain circumstances. According to *Horn's*

Principle of Group Foraging, animals benefit from maintaining and defending individual territories when food resources are evenly distributed. However, when food resources are not evenly distributed, and unpredictable, animals benefit from foraging as a group. Groups benefit from the previous knowledge of individuals within the group, increasing the likelihood that any one group member will locate food on a given day. Therefore, some animals may not live as a cohesive group for the duration of their lives; instead they create microterritories located near a centralized location which then allows the animals to forage more or less as a group (Wilson 2000).

The Evolution of Communication and Cooperative Foraging

For communication to develop in the context of cooperative foraging, there must be two categories of individuals: signalers, who alert others to located food resources (i.e., cooperators), and non-signalers (i.e., noncooperators), who may respond to signals but do not signal to others. Individuals who receive emitted signals, and are not currently located in a superior location, will relocate in order to exploit the signaled resources. When altruistic communication directly benefits the recipient, but not the donor, it is considered to be cooperative communication, which is to be separate from inadvertent information sharing. Cooperative communication, which can be expressed in the form of recruitment calls, is issued when food resources are located. Despite the apparent benefit of keeping the resource to one's self, individuals recruit conspecifics to benefit from the located resource. Although this initially appears to be an altruistic endeavor, evaluations of this strategy demonstrate that through recruiting others, individuals effectively increase the number of animals issuing recruitment calls within a centralized area – thus increasing the efficiency with which resources are located and exploited within that area (Torney et al. 2011).

Conclusion

Cooperative foraging is considered to be a driver of evolution not only because of its cognitive requirements but also due to the resulting increase in individual fitness (Wilson 2000). Still, there are disagreements as to the relative benefits of cooperative foraging. Clark and Mangel (1986) argue that theories aimed at understanding cooperative foraging underemphasize group hierarchical structures, in-group competition, and environmental conditions which may mitigate the overall benefits of cooperation. For example, decreased individual vigilance within groups could alternately be explained as being a result of intragroup competition for food resources, area to cover, and variations in foraging ability rather than the assumed vigilance of other animals in the group (Vasquez 1997).

While there may be some merit to these concerns within certain contexts, complex species such as bottlenose dolphins (*Tursiops truncatus*) and chimpanzees (*Pan troglodytes*) demonstrate that social hierarchies may actually facilitate cooperative foraging as demonstrated by both a division of labor and a specialization of roles within foraging groups (Gazda et al. 2005) as well as food sharing (Gilby 2006). Similar observations have been made in Arabian babblers (*Turdoides squamiceps*). In this species, it has been observed that hierarchies not only play a role in selecting foraging strategies, but subordinate animals may even demonstrate more flexible behaviors in order to make use of novel foraging opportunities (Keynan et al. 2015). Clark and Mangel (1986) are correct in asserting a need to evaluate individual occurrences of cooperative foraging when determining how that behavior has evolved and its overall benefit to the organisms concerned.

Cooperative Grooming

Karin Schneeberger

University of Bern, Bern, Switzerland

Synonyms

[Allogrooming](#); [Allopreening](#); [Mutual grooming](#); [Reciprocal grooming](#); [Social grooming](#)

Definition

In contrast to autogrooming during which an individual cleans itself, cooperative grooming is defined as a social act during which an animal grooms a conspecific, usually implying costs to the groomer and benefits to the groomee.

Introduction

Grooming functionally serves different hygienic purposes such as removing dead skin and parasites. Therefore, it is an important part of hygienic routine in most animals and is strongly associated with survival. In many species, individuals do not only groom themselves but are also frequently observed grooming conspecifics (reviewed in Spruijt et al. 1992) or even individuals from other species (cleaning symbiosis; Poulin and Grutter 1996). Within species, besides increasing hygiene, allogrooming relaxes the receiving individual, serves as appeasement gesture to reduce aggression between partners, can be part of courtship behavior, and facilitates social bonds such as between mother and offspring or between individuals of a social group. However, allogrooming

Mechanisms and examples of cooperative grooming

When grooming themselves, individuals can not always reach all parts of their body and thus depend on the help by conspecifics or specialized symbionts (e.g., cleaner fish; Poulin and Grutter 1996). In the latter case, the cleaner removes and eats parasites, dead skin, and other material from the surface of a host organism (the client), and thus grooming is of mutual benefit for both the donor and receiver. However, allogrooming among conspecific can usually not be explained by immediate benefits for the donor but is still one of the most commonly observed social interactions in many animals (Spruijt et al. 1992). In fact, time spend in grooming a conspecific has to be traded off against predator vigilance or foraging, both which would increase the fitness of an individual. Similar to other altruistic behavior, allogrooming therefore is costly for the donor, and scientist have been searching for explanations on why this behavior evolved.

If animals groom individuals which they are related to, such altruistic behavior can be explained by kin selection (Hamilton 1964): An individual gains fitness by helping a conspecific sharing proportions of the same genes (i.e., siblings). After all, overall fitness or inclusive fitness is defined as the sum of own reproduction and the reproduction of relatives in comparison with the total reproductive output of the population. Thus, helping relatives promotes an individual's relative genetic representation in the gene pool in the next generation.

However, animals do not only groom relatives but also conspecifics which they are not related to. Direct reciprocity is one potential mechanism that may establish cooperative grooming among

nonkin. Impalas (*Aepyceros melampus*), for example, groom each other in the head and neck area (Hart and Hart 1992), a behavior which is directly reciprocated between individuals, i.e., the receiver of a grooming bout will return the favor to the previous groomer. Notably, in some species, grooming can not only be reciprocated with grooming but may be exchanges for other services. In the common vampire bat (*Desmodus rotundus*), for example, allogrooming is correlated with food sharing among individuals (Wilkinson 1986), and female baboons (*Papio ursinus*) can trade grooming for support during aggressive interactions and other valuable commodities (Barrett et al. 1999).

Thus, beyond hygiene, allogrooming may reflect the characteristics of the social relationship between donor and receiver and thus have important social functions. The structure and function of allogrooming relationships have mostly been studied in primates, such as in capuchin monkeys (*Cebus apella*; Bitetti 1997). Here, dominant males and females do engage more in allogrooming than subordinates, and females with infants are especially attractive grooming partners. Recently, potential social functions have been described in nonprimate species as well, such as in the cooperatively breeding meerkat (*Suricata suricatta*), where grooming may help to maintain beneficial social relationships and indicate the value of subordinate breeding helpers (Kutsukake and Clutton-Brock 2010). Through enhancement of the social position within a group, allogrooming individuals can thus increase their fitness via other benefits such as social support.

In humans, besides during child care, mutual grooming among is mostly directed to romantic partners, being of importance for courtship, developing trust, and as a potential indicator for parental investment (Nelson and Geher 2007).

Conclusion

Cooperative grooming is part of hygienic routine in many animals and is often reciprocated

between individuals. Besides, it has important social functions, such as during courtship or by establishing and maintaining social bonds. While cooperative grooming is common in other mammals, there are only few studies on humans where grooming is mainly observed as part of child care and between romantic partners.

Synonyms

Reproductive competition among members of the same sex

Definition

Competition that takes place during coitus between members of the same sex to control fertilization and reproduction.

Introduction

Contrary to the impression that is created by the fact that men and women often have radically different reproductive best interests, males and

females do not typically compete with each other for fitness. When it comes to reproductive competition, males compete with other males for paternity, and females compete with other females to attract high quality mates who in the case of humans will enter into a long-term committed relationship (i.e., a pair bond) that includes protection and provisioning of the female and her offspring. In other words, reproductive competition among humans is often intrasexual rather than intersexual.

For most sexually reproducing species the males' role in reproduction is simply to provide a complementary set of gametes, and therefore insemination represents the end point in the reproductive process. However, for females, particularly mammalian females, insemination is the mere beginning of the reproductive process which in the case of humans can last for years or even decades (e.g., pregnancy, childbirth, breast feeding, child rearing).

In the strict sense of the term, copulatory intrasexual competition involves competition among members of the same sex that occurs in the context of copulation. Examples include evolved mechanisms related to sperm competition that enable males to adjust the contents of an ejaculation to take into account the possibility that the female may have viable semen in her reproductive tract left by former males, or that she may be likely to have sex with other males in the near future. Among females, copulatory intrasexual competition could include changes in the strength and frequency of orgasm and/or the timing of intercourse so as to make conception more or less likely when having sex with certain males (see entry on ► [“Female Copulatory Orgasm”](#)).

To illustrate some of the intricacies of intrasexual competition, a good example is the concept of human paternal assurance tactics, with particular emphasis on counter insemination tactics.

Human Paternal Assurance Tactics

When it comes to genetic assurance, females have an enormous advantage over males. Maternity is

always certain. Females have an iron clad guarantee of sharing 50 % of their genes in common with each of their children. But largely as a consequence of female infidelity, the probability of paternity is rarely certain and males have to contend with the prospect of being cuckolded; i.e., duped into caring for children sired by other males (see entry on ► [“Cuckoldry Risk”](#)).

Gallup and Burch (2006) identified and developed a refined analysis of four evolved strategies that men use to maximize the likelihood of paternity, or conversely to minimize the chance of being cuckolded. These tactics exist as a set of sequentially dependent strategies which begin with “Insemination Prevention Strategies” that function to preclude or at least minimize the likelihood that their committed partner will be inseminated by other males. These include mate guarding (Buss 2002), mate sequestering, mate monitoring, and male sexual jealousy (Daly and Wilson 1982). Other techniques used to discourage or preclude female infidelity include chastity belts and infibulation as barrier methods, or surgical removal of the clitoris designed to diminish any interest the female may have in engaging in sex with other males. It has also been suggested in this context that males who insist on having high frequency sex with their female partners do so to minimize the likelihood of partner infidelity by keeping their partners sexually satiated (Shackelford 2003).

However, should these tactics fail and the female is inseminated by another male, men then employ “Counter Insemination Strategies” which include sperm competition (e.g., Shackelford, 2003) and semen displacement (Baker and Bellis 1995). These function to reduce the likelihood of conception by the rival male (see entries on ► [Evolutionary Arms Race](#) and ► [Tactics to Solve Adaptive Problems of Sperm Competition](#)).

Should these mechanisms fail and the female is impregnated by another man, the next category of paternal assurance strategies involves “Pregnancy Termination Tactics” which can involve pregnancy-induced domestic violence that terminates the pregnancy (Burch and Gallup 2004), or vigorous sex that leads to coitus-induced uterine contractions which interfere with embryo

implantation (for details see Gallup and Burch 2006). Finally, if the pregnancy prevails and a child is born, the remaining class of paternal assurance strategies involves “Postpartum Investment Strategies” where the resident male adjusts his investments in the child in relationship to the probability that they share genes. These strategies can range from instances of genuine investment, to indifference, neglect, abandonment, child abuse, or even infanticide. There is growing evidence, for example, that males are sensitive to paternal resemblance and invest preferentially in infants with whom they share facial features (Platek et al. 2002). Recent evidence shows that in addition to shared physical features, shared interests and attitudes as behavioral phenotypes that may also be mediated by genes also appear to promote greater paternal investment by fathers (Gallup et al. 2016).

Semen Displacement

Sperm competition is the most frequently investigated form of intrasexual competition among males. In the case of humans, however, semen displacement has emerged to aid and abet more traditional instances of sperm competition. As suggested initially by Baker and Bellis (1995), there is now evidence that the configuration of the human penis has evolved to purge or displace semen recently left by other males from the female reproductive tract to enable the resident male to substitute his semen for those of his rivals (see entry on ► [“Evolutionary Arms Race”](#)).

Attempts to simulate sexual encounters under laboratory conditions using artificial genitals show that variation in penis morphology as it relates to the glands and the coronal ridge is related to semen displacement (Gallup et al. 2003). How the penis is used during sex also affects the magnitude of semen displacement; i.e., evidence suggests that the depth of insertion of the penis into the vagina is proportional to how much semen is removed. Consistent with the results of these laboratory simulations, follow-up studies (appearing in the same paper) of college students in committed sexual relationships

showed that under conditions that raise the prospect of female infidelity, males react by engaging in deeper and more vigorous thrusting.

The Topping-Off Hypothesis

Another potentially important dimension of copulatory intrasexual competition is emerging evidence in human males for context specific mechanisms that adjust the composition of the ejaculate on an occasion by occasion basis to fit the male's reproductive best interests (see entry on ► [“Seminal Plasma”](#)). For instance, the quality of semen samples obtained through masturbation (as measured by sperm count and sperm motility) is greater for males who watch sexually explicit videotapes than for those who have to rely on their imagination (Yamamoto et al. 2000). Higher quality ejaculates are also obtained from semen donors who watch sexually explicit films of novel as opposed to familiar women (Joseph et al. 2015). Moreover, in contrast to harvesting semen samples through masturbation, samples obtained using coitus interruptus are of greater quality (Zavos et al. 1994).

Rape may represent another instance in which there are changes in the chemical properties of the human ejaculate. In an attempt to explain the increased risk of conception as a consequence of rape as opposed to consensual sex, Burch and Gallup (2006) speculate that there may be mechanisms operating at the level of male reproductive biology that adjust the concentration of female sex hormones in seminal fluid to make induced ovulation as a result of sexual assault more likely. Rather than a matter of idle armchair speculation, Burch and Gallup identify what appear to be the hormones in seminal fluid that could trigger ovulation and outline several ways to test this hypothesis by conducting assays on semen samples obtained from rape victims or from semen donors who watch nonconsensual pornography (see entry on ► [“Seminal Plasma”](#)).

Conclusion

Reproductive competition among men typically takes the form of competition for paternity. Reproductive competition among women often involves competition for exclusive access to a high status/high quality man who will enter into a pair-bonded relationship with the women which will insure for the protection and provisioning of the woman and her children.

Copulatory Plugs

Andreas Sutter

University of Exeter, Penryn, United Kingdom

Synonyms

[Mating plug](#); [Sperm plug](#); [Sphragis](#); [Vaginal plug](#)

Definition

Plugs consisting of coagulated semen or parts of male genitalia that are deposited in the female genital tract during or after mating.

Introduction

Copulatory plugs are taxonomically widespread, having been described in nematodes, insects, arachnids, amphibians, reptiles, and mammals. Copulatory plugs are often interpreted as male adaptations to male-male reproductive competition. Preventing or delaying female remating with rival males can increase the paternity success of males that deposit copulatory plugs. However, copulatory plugs may well serve other non-mutually exclusive functions.

Taxonomical Variation

There is great variation in the composition, size, and origin of copulatory plugs among animal taxa. Amorphous copulatory plugs are composed of seminal fluids that are excreted by male accessory glands, as is the case in the majority of taxa. The substances that form the plug are secreted by one or several of the accessory glands. Once transferred to the female, these seminal fluids coagulate into a gelatinous or waxy substance. In many taxa, copulatory plugs represent a considerable male investment. For example, in butterflies, males of some species transfer very large copulatory plugs that make up a large proportion of the ejaculate (Simmons 2001). In some spider species, males sacrifice parts of their genitalia or even their whole body (after dying a programmed death) in order to obstruct female genitalia (Uhl et al. 2010).

Paternity Protection

Research on copulatory plugs has strongly focused on their potential adaptive role in male-male reproductive competition. When females mate with multiple males, males may benefit from preventing or delaying female remating, especially when the last-to-mate male fertilizes the majority of a female's ova (Parker 1984). Copulatory plugs may represent a barrier to rival

males and reduce female attractiveness or sexual receptivity. However, selection on rival males to remove copulatory plugs and on females to resist chastity enforcement likely prevents copulatory plugs from being fully effective. For example, females may contribute secretions that degrade deposited plugs (Mangels et al. 2015), thus potentially influencing the male's fertilization success. Conflict between males and between the sexes thus leads to coevolutionary dynamics of plug effectiveness (Fromhage 2012), and extant species may represent snapshots of different stages of these dynamics. Indeed, while there is mounting evidence for a role of copulatory plugs in male-male competition from across species comparisons (Dixon and Anderson 2002; Ramm et al. 2005; Simmons 2001), direct experimental evidence is mixed and shows considerable variation in plug efficacy across different species. However, incomplete chastity enforcement does not mean that males do not benefit from depositing plugs, as partial prevention or temporal delay of female remating can represent a considerable paternity benefit.

Other Functions

In addition to paternity protection, copulatory plugs may serve other reproductive functions, such as promoting sperm transfer and transport, gradual sperm release, preventing sperm leakage, and triggering female physiological responses to mating (Avila et al. 2015). Depending on the effect of the copulatory plug, the interests of males and females may be opposing or aligned. In their extant state, copulatory plugs may be necessary for successful reproduction in many species, but understanding the evolutionary origins of copulatory plugs is a complex task. Recent research has started to elucidate the relative importance of copulatory plugs in male-male reproductive competition and the rather cryptic influence of females through assisting or resisting plug deposition, formation, and removal (e.g., Aisenberg and Eberhard 2009; Friesen et al. 2016).

Conclusion

Copulatory plugs represent a convergent male strategy for paternity protection against rival males in many animal taxa, but likely serve additional, nonmutually exclusive functions. Evolutionary dynamics of conflict and cooperation between males and females result in variation in the effectiveness of plugs for paternity protection.

Co-residence and Early Maternal Perinatal Association

Jan Antfolk and Helena Godenhjelm
Department of Psychology, Åbo Akademi
University, Turku, Finland

Synonyms

[Kin recognition](#); [The Westermarck effect](#)

Definition

Co-residence and early maternal perinatal association are two important kinship cues for identifying siblings.

Introduction

Although kin selection, inbreeding avoidance, and cooperation and conflict within the family do not necessitate an ability to identify another individual as a sibling, kin recognition is believed to be a central mechanism in the individual development of kin-directed social behavior in humans (e.g., Penn and Frommen 2004). Concerning siblings, two important kinship cues are co-residence and early maternal perinatal association.

The Westermarck Effect

Human kin recognition is thought to rest largely on environmental information, and this kin recognition can be direct (e.g., phenotype matching) or indirect. Co-residence and maternal perinatal association are two indirect kinship cues humans use to identify siblings. In 1891, Westermarck

hypothesized that two individuals living closely together during childhood will develop a sexual aversion toward each other. Because individuals living closely together during childhood tend to be genetically related (i.e., sibling or half-sibling), this aversion is, in most cases, an aversion toward sex with a sibling. There is a large body of evidence corroborating this hypothesis (see Rantala and Marcinkowska 2011 for a review). Studying arranged marriages in Taiwan, Wolf (e.g., 1970) compared two forms of marriages. In one type of marriage, the to-be couple lived together from childhood, and in the other type of marriage, the couple lived together only as adults. Wolf found that the divorce rate was higher and the fertility rate was lower when the arranged marriages included childhood cohabitation. Similar results of childhood cohabitation have been found in other populations. This includes unrelated individuals raised together in Israeli kibbutzim (e.g., Shepher 1971; Spiro 1958; Talmon 1964) and marriages between cohabiting patrilineal cousins in Lebanon (McCabe 1983) and Morocco (Walter 1997). Bevc and Silverman (1993) also showed that duration of co-residence between purported siblings was negatively associated with sibling incest. It has also been shown that moral judgment of third-party incest is harsher if the two incestuous individuals are described as having lived closely related in childhood (compared to living apart) and that this effect is particularly strong if there is no other evidence of genetic relatedness between the two individuals (Antfolk et al. 2012). In sum, childhood co-residence affects sexual behavior, decreasing sexual interest between individuals living closely together in childhood. As such, co-residence seems to operate as one mechanism leading to inbreeding avoidance between siblings.

Co-residence and Altruism

Shared co-residence also affects altruism (i.e., social behaviors that supports the well-being of another individual while coming at some cost to the altruistic individual). Altruism – contrary to

inbreeding aversion – is also affected by perceptions of reciprocity and trustworthiness. Because of this, altruistic behavior also includes other benefactors than kin. Nevertheless, costly altruistic acts are more likely to be directed to kin compared to close friends (Kruger 2003; Stewart-Williams 2007). In line with this, research suggests that when two individuals are raised together, and thus very likely to be related, feelings of emotional closeness no longer predict altruistic dispositions; between unrelated individuals, emotional closeness is, however, positively associated with altruistic dispositions (Lewis 2011). Also among unrelated individuals, duration of the co-residence habitation is positively associated with higher levels of altruism (Lieberman and Lobel 2012). Full siblings co-residing through childhood also show higher levels of investment in each other compared to half-siblings or non-related siblings (Pollet 2007; White and Riedman 1992). Bressan et al. (2009) examined how different types of altruism are influenced by different types of kinship cues. The authors found that both full siblings and half-siblings that had co-resided were more willing to help each other. The effect of co-residence with a half-sibling was independent of variations in emotional closeness (Bressan et al. 2009). Lieberman et al. (2007) even found that co-residence through childhood predicted altruism more so than siblings' consciously held beliefs about their genetic relatedness (Lieberman et al. 2007). In a recent study by Lieberman and Billingsley (2016), it was found that co-residence duration works as a proxy of shared parental investment, which, it could be argued, is the second most reliable kinship cue following early maternal perinatal association.

Co-residence Between Other Family Members

While co-residence originally was believed to be a kinship cue only used to identify siblings, some research also suggests it is used in other kin dyads as well. Here, studies have focused on paternal identification of their biological children. Studying men in the military, Williams

and Finkelhor (1995) found that involvement in caretaking, which usually prerequisites cohabitation, lowers fathers' incestuous attraction toward their daughters. Although this finding is in line with co-residence acting as a kinship cue also in father-daughter relationships, the study failed to effectively exclude possible confounds. For example, men in the military, who spend a lot of time away from their child's mother, will also be more likely to worry about cuckolding.

Interestingly, studying ethnographic information on fathers co-residing with either biological or stepchildren from a rural Trinidadian village, Flinn (1988) found that not only did fathers interact more frequently and less agonistically with their biological children: The duration of co-residence (and co-residence at birth) with stepchildren was associated with lower rates of interaction and higher rates of agonistic interaction (Flinn 1988). Hence, co-residence per se does not seem to act as an independent kinship cue for fathers. Two interesting possibilities remain. Firstly, co-residence might function as a dependent kinship cue, that is, provide information about relatedness if another cues are present simultaneously. Secondly, co-residence might directly increase altruism between two individuals, that is, affect social behaviors without affecting beliefs about relatedness. Regarding the first possibility, very little is known. Studies suggest that the perception of the mother's sexual fidelity (Apicella and Marlowe 2004) and phenotypic similarity (e.g., Alvergne et al. 2007, 2009; DeBruine 2004) are important kinship cues for fathers. Concerning the other possibility, studies suggest that co-resident fathers provide more parental investment (Carlson and Berger 2011). Quite naturally, co-resident biological parents have vital effects on children's well-being (e.g., Tooley et al. 2006). Furthermore, children co-residing with both biological parents receive more parental investment than children living with a single parent or a biological mother and social father (Carlson and Berger 2011).

Much less is known about whether co-residence is a kinship cue used by children to identify their parents. A retrospective study of adults, however, suggests that co-residence with adults may regulate children's perception of relatedness to adults and modulate social behaviors accordingly (Antfolk et al. 2014).

Early Maternal Perinatal Association

In most mammals including humans, internal gestation, birth, and breastfeeding provide a very reliable kinship cue between a mother and her offspring. If a child were to remember this early physiological and nutritional connection to their mother, the child could be fairly certain that the woman giving birth is the biological mother. An older sibling witnessing this early maternal perinatal association between the individual identified as a mother and a new child can, likewise, be fairly certain that this new child is a maternal sibling. For older siblings this cue provides very reliable information about maternal relatedness. For younger siblings this cue is not available. In 2007, Lieberman, Tooby, and Cosmides showed that co-residence regulates social behavior only in younger siblings. Older siblings, who can see their own mother caring for a younger individual, can use this as a kinship cue instead and do not need to rely on the presumably less valid cue of co-residence: Only in younger siblings was co-residence associated with sibling altruism and inbreeding aversion (Lieberman et al. 2007). In fact, if a sibling can use early maternal perinatal association as a cue, co-residence duration is no longer used. Co-residence duration strongly affects altruism and sexual aversion between siblings in the absence, but not in the presence, of maternal perinatal association. Maternal perinatal association significantly predicts altruism toward younger siblings, even when controlling for co-residence. Moreover, early maternal perinatal association predicts altruism toward younger siblings better than having the same mother or sibling co-residence beginning at the sibling's birth (Lieberman et al. 2007). Szynycer and colleagues'

(2016) cross-cultural study supports these findings: Both maternal perinatal association and co-residence are used as kinship cues in siblings.

Asymmetric Relatives

Co-residence but not maternal perinatal association can be used to identify paternal half-siblings. Simultaneously, maternal perinatal association is an equally strong cue for maternal half-siblings as it is for full siblings. Because of this, it is possible that not only the age difference between siblings (older vs. younger) modulates the effects of co-residence. It is also possible that lineage (full siblings and maternal half-sibling vs. paternal half-siblings) modulates the effects of co-residence. Unfortunately, to date, no study has been designed to specifically test this possibility. We predict that younger siblings depend on co-residence in both the identification of full siblings, maternal half-sibling, and paternal half-siblings, but that older siblings rest on maternal perinatal association when identifying full siblings and maternal half-siblings, but rely on co-residence when identifying paternal half-siblings.

Conclusions

Childhood co-residence is used as a kinship cue in younger siblings. It regulates inbreeding avoidance and altruism. Older siblings rely on maternal perinatal association. Alongside these two cues, other cues may also increase or decrease inbreeding aversion and altruism between siblings. It is currently unclear whether co-residence and maternal perinatal association are used as kinship cues in other relationship types. It is also currently unclear whether maternal perinatal association is employed only in the identification of full and maternal half-siblings.

Definition

Corresponding relationships between fear and different neurobiological and psychological constructs.

Introduction

Fear is an innate and universal emotion which, throughout development, generates adaptive responses to various situations. In this process, neurobiological mechanisms are activated in the face of threatening situations and/or stressors, and some individuals are more predisposed than

others to be reactive to these threats, and thus, to have a response to fear (anxiety).

Neurobiological Correlates of Fear

The amygdala, in addition to being related to the function of survival, is a key component for emotional processing and for the way we respond to the emotions of others. It is mainly associated with the processing and behavioral response to fear and threatening stimuli and, consequently, to anxiety symptoms (Moul et al. 2012). It is a component that acts in multiple circuits to give support to several psychological functions. In addition to its central role in the recognition of internal emotions and the emotions of others, the amygdala functions in a circuit related to the hypothalamus (HPA axis), responsible for mediating our responses in threatening situations. These responses are gradual, depending on how close the threat is, ranging from freezing, to flight, to fighting. Thus, when the threat is very close, making it impossible to freeze or escape, there is an increase in neural activity in this circuit, which leads to a more superficial cognitive processing, increasing the probability of reacting aggressively (Blair et al. 2014).

The activation of the HPA axis occurs from the perception of a threat, which is then processed in the limbic system by the amygdala and the hypothalamus, leading to the activation of the pituitary gland and then the adrenal gland, to produce cortisol. Cortisol is released into the cortex, and its function when faced with stressful situations is to suppress several metabolic processes, facilitating the use of coping strategies in front of the stressor (Corbett and Simon 2014).

Another point to be considered regarding responses to exposure to threat stimuli are the changes in the autonomic nervous system, which is one of the regulators of several physiological processes that allow fight or flight responses, and also responsible for bodily changes that are common responses to anxiety, such as dry mouth, sweating, and intestinal alterations.

The autonomic nervous system (ANS) consists of two systems: the parasympathetic nervous system (PSNS) and the sympathetic nervous system (SNS). The PSNS is involved in daily activities, promoting a calm behavior and vegetative and routine activities, while the SNS is activated when a stressor is perceived (Sapolsky 1998). When faced with stress, the vagus nerve is deactivated, suppressing metabolic demands and facilitating fight or flight reactions by accelerating the heartbeat and activating the sweat glands, increasing the level of skin conductance. In restful situations, the vagus nerve slows down the heart rate, facilitating engagement in social activities (Porges 2007).

The activity of the vagus nerve is measured by the variability of the heart rate, from the fluctuation of the intervals between beats. At stress peaks, variability falls because of the deactivation of the vagus nerve. Thus, the break from the variability of the heart rate allows individuals to select more actions to react to environmental demands, if necessary. Moreover, this is indicative of adequate self-regulatory skills (Porges 1992).

Cognitive Processing in Fear-Related Mental Disorders and Its Maintenance

Several hypotheses have tried to explain the cognitive processing involved in anxiety-related disorders. However, we will describe in more detail Beck and Clark's (1997) models for anxiety disorders and the Foa and Kozak's (1991) model for emotional processing. As previously mentioned, our body emits a fear response from the preappraisal of internal or external stimuli, which generates anxiety symptoms. Fight, flight, or freeze responses may be issued to maintain the physical and psychological integrity of the individual against the threat. Beck and Clark's (1997) cognitive model of anxiety describes the cognitive processing of high anxiety from the perspective of vulnerability. This perception would arise from the individuals' understanding that they are subject

to internal or external threats, which they have no control over, and they perceive themselves as unfit to deal with the threat (Beck and Clark 1997). Also, this first appraisal involves overestimating the possible danger of the threat. This, coupled with a second reappraisal, in which the individual considers himself or herself to be less able or to have few resources to cope with the threat, would result in high anxiety (Beck & Clark), which can reach clinical levels such as panic disorder, social anxiety disorder, generalized anxiety disorder, or post-traumatic stress disorder.

In general, the cognitive processing described by the authors involves a trigger situation or stimulus, such as an expression of anger or fear, which activates the primitive threat mode, involving the HPA axis, attentional bias, thoughts and images related to the threat (including memories), and immediate inhibitory or defensive responses (fight, flight, freezing), then a more elaborate reappraisal (distorted in highly anxious individuals), and finally, anxiety symptoms (Beck and Clark 1997). In turn, anxiety symptoms reawaken the fear activation mode, since the presence of anxiety is perceived as a threat, for example, in panic disorder (e.g., "I'm going to go crazy"), generalized anxiety disorder (e.g., "I'm very nervous, I won't be able to do anything"), and social anxiety disorder (e.g., "I'm anxious and everyone will notice").

One of the central mechanisms used by individuals with anxiety disorders for the immediate relief of symptoms and, consequently, their maintenance is avoidance. Avoiding trigger situations and anxious thoughts by itself already causes the individual not to initiate the process of appraisal and, consequently, of perception of increased danger and of low effectiveness against the threat. Processes such as cognitive avoidance, distraction, worry, and suppression of thoughts can be described as avoidance mechanisms. Still, it is described as having a central role for the disassociation of the stimulus to fear and the cognitive restructuring of the stimulus (Beck and Clark 1997).

Thus, avoidance maintains the association of fear with the stimulus or situation, since the individual is not exposed to it until the anxiety

naturally decreases, and then disassociation can occur between the stimuli and the physiological and cognitive habituation to anxiety. The avoidance process can even lead to an increase in trigger stimuli and in the anxiety generated by them, since it facilitates distorted thoughts such as generalization (Clark and Beck 2012). For example, an individual who was assaulted by a man in red might start by avoiding people with a face similar to the thief, evolving to individuals with red t-shirts; however, over time, he will avoid any red objects so as not to run the risk of activating his fear system and having anxiety symptoms.

The emotional processing theory by Foa and Kozak (1991) proposes that the cognitive structure of fear would be represented by a schedule so that it would be possible to escape danger. This programming would be based on "what" we are afraid of (the stimulus, trigger), its responses (e.g., accelerated heartbeat, trembling), and the associated meaning (e.g., trembling means I am afraid). The authors emphasize that in situations where appraisal of risk and of the ability to cope with the threat is realistic, fear is an adequate and normal reaction (Rothbaum et al. 2007). However, this reaction would become inadequate when the structure does not accurately represent reality, when fear and avoidance responses are elicited by simple and/or harmless stimuli, seen as dangerous, and when fear reactions interfere with the person's day to day (Rothbaum et al. 2007). Thus, it is emphasized that the activation of fear, and therefore of anxiety symptoms, is necessary for realistic information to replace nonrealistic ones in the structure of fear, for example, "I will not survive."

In the case of post-traumatic stress disorder (PTSD), the authors propose that the disorder would develop from a failure in the emotional processing of a traumatic memory; the recovery of a fear-generating memory in a safe environment would promote realistic information about the costs and consequences of fear, thus reprogramming the structure of fear. Thus, being exposed to traumatic memories can generate habituation to anxiety, and reformulate it as a single episode in space and time rather than

continuous in the present, increasing the individual's ability to survive it (Rothbaum et al. 2007).

Considering the theories of Beck and Clark (1997) and Foa and Kozak (1991; Rothbaum et al. 2007), it is possible to identify connections between both, and overlaps between anxiety disorders (Beck and Clark 1997) and specific fear-processing disorders resulting from traumatic events (Rothbaum et al. 2007). These aspects may allow a better understanding of the symptomatology related to the processing of threat stimuli, since it integrates environmental components, cognitive, psychophysiological and the necessity of exposure to them so that it is possible to restructure and reappraise the threat, coping skills to deal with it and its consequences.

Conclusion

From an evolutionary psychology perspective, this entry intended to describe fear and its adaptive function in human beings, as well as some of its neurobiological characteristics and the processing and maintenance of disorders related to threatening stimuli. The importance of early identification of situations of vulnerability and of early stress is emphasized, so that a hyperactivation of the HPA axis is avoided, which may be protective for the development of anxiety disorders and disorders related to trauma and stress throughout development and adulthood.

Definitions

Cortical neurons are the neurons present in the cerebral and cerebellar cortex.

Neurons or nerve cells are electrically excitable cells that receive and transmit impulses (such as action potential).

Conduction velocity is the velocity at which impulses are transmitted along an excitable tissue.

Introduction

Neurons form the basic building blocks of nervous system. It is believed that neurons have evolved from primitive cells, which used to respond to various stimuli by contracting. Neurons have evolved and developed to perform the function of integrating and transmitting nerve impulses. Broadly the brain parenchyma contains two types of cells (neuronal cells and glial cells). The neuronal cells have a unique structure. Specific regions of the neuron deliver specific functions (Fig. 1).

The axonal processes of many neurons are myelinated. This means that the axon is covered

by a sheath of myelin which is a protein lipid complex. In the central nervous system, neurons are myelinated by oligodendrocytes. The oligodendrocytes send out multiple processes which are responsible for myelination on multiple neighboring axons (Barret et al. 2012).

Glial cells are non-neuronal cells, which have important roles as connective tissue (astrocytes), immune functions like phagocytosis (microglia), as well as myelination of neurons (oligodendrocytes). Myelination facilitates conduction of impulses, in addition to subserving functions like neuronal repair and metabolism of neurotransmitters. Glial cells have the ability to divide and proliferate in adulthood, unlike nerve cells. The glial cells myelinate axons, and this was a crucial step in the evolution of nervous system in vertebrates. They are responsible for maintaining the integrity of the axons in a long-term basis. The glial cells also perform key functions which are essential for normal neurogenesis, neuronal growth, and circuit refinement (Casano and Peri 2015; Nave 2010).

The cortical neuronal integrity is responsible for the cognitive functions, consciousness, as well as perception of senses (Molyneaux et al. 2007).

Cortical Neurons and Conducting Velocity, Fig. 1 Structure and function of the neuron

All these processes are carried out through functional connectivity of different brain regions with cortex as well as the amount of synapses established. Astrocytes help in formation of synapses between neurons (Farhy-Tselnick and Allen 2018). The electrophysiological characteristics of the cortical neurons are influenced by the degree of dendritic complexity (Zhu et al. 2016). Glial cells are closely associated with the functioning of the cortical neurons.

Conduction velocity is an important electrophysiological property of excitable tissues like neurons. In the brain, it is regulated through the neurons in coordination with glial cells associated with them.

Cerebral Cortex: Evolution and Development

The highly convoluted gray matter which forms the outermost part of cerebrum is what constitutes the “cortex.” Human brain has evolved over 300 million years, and the cortex has developed significantly in comparison other hominids, which is responsible for extraordinary cognitive capacity in humans. The cortex constitutes of billions of neurons and a larger number of glial (supporting) cells and other cells (Carter 2014). The cytoarchitecture of cerebral cortex comprises of distinct regions, which has become more complex during the human cerebral evolution; furthermore novel areas have also evolved. Gene regulation has played a crucial role in this evolutionary process. The *Homo sapiens* are in a higher stage of evolution and have well developed brain. Their brain’s extraordinary potential is attributable to the degree of cortical expansion during the early developmental stages through complex neural interaction, migration, and proliferation of neural stem cells (Kriegstein et al. 2006).

Mammalian cerebral cortex primarily contains two broad classes of neurons:

1. Pyramidal neurons which project to other regions of the brain.

2. Non-pyramidal neurons which are interneurons in the cortex.

Neurons in the brain develop from radial glial cells (located in ventricular zone) and intermediate progenitor cells (located in sub-ventricular zone). These neurons subsequently migrate to various zones including cortical plane in a sequential manner (Molyneaux et al. 2007; Noctor et al. 2004). The glutamatergic projecting neurons in the cortex develop from the progenitor cells present in the dorsolateral telencephalon, whereas the GABAergic interneurons in the cortex originate from the progenitor cells present in the ventral telencephalon (Molyneaux et al. 2007). This process of migration is very important for normal cerebral function. Abnormalities in neuronal migration can result in neurodevelopmental disorders (Geschwind and Rakic 2013; Parnavelas 2002).

Cortical Neurons: Types and Organization

The cortical neurons are organized within the cerebral cortex in horizontal layers and vertical or radial columns which form the cytoarchitecture of the cortex. Important cortical neurons include:

- (I) Pyramidal cells: These cells are the most common type of neurons in the cortex and constitute 65% of all cortical neurons. They are excitatory neurons and project out of their local area to distant target regions of the brain and hence also known as projection neurons. Their primary neurotransmitter is glutamate.
- (II) Spiny stellate cells: These neurons are also excitatory and are local interneurons. They make up 20% of cortical neurons. Glutamate is the primary neurotransmitter here too.
- (III) The remaining 15% is constituted by local inhibitory interneurons, and majority of them are GABAergic.

Typically the cortex is said to have six layers (Molyneaux et al. 2007):

- I. *The molecular/plexiform layer*: It contains very few cells. It is mainly composed of the axonal and dendritic processes of various cells including neurons outside the cortical area, cortical interneurons, and the pyramidal neurons in other layers of the cortex. In stained section, this layer appears as a narrow band of fibers lying horizontally.
- II. *The external granular layer*: It contains both pyramidal and non-pyramidal cells. On stained section, it shows vertically arranged fibers traversing the layer.
- III. *The external pyramidal layer*: It contains mainly pyramidal cells, along with scattered non-pyramidal neurons. Similar to layer II, myelin stain shows vertical fibers in this layer.
- IV. *The internal granular layer*: This is the narrowest layer. It contains a dense population of non-pyramidal cells. In stained section, a prominent band of horizontal fibers can be seen. This band is also known as *outer band of Baillarger*.
- V. *The internal pyramidal layer*: The size of pyramidal neurons increase from the superficial to deeper layers of the cortex, and this layer contains the largest pyramidal cells. This layer also contains non-pyramidal cells, and in stained section vertical fibers are seen. A prominent central band of horizontal fibers is also seen. This band is known as *inner band of Baillarger*.
- VI. *The multiform layer*: This contains neurons of different shapes, and the layer blends with the white matter below.

The interneurons in the cortex are responsible for interconnections between local (cortical) neurons, whereas the projection neurons in the cortex are responsible for connecting distant cortical structures as well as cortico-subcortical connections. The projection neurons also establish

connection with extra-cerebral structures (e.g., brain stem, cerebellum) (Molyneaux et al. 2007). There are some regional variations in the cortical structure, with some regions lacking certain laminae (layers); these are referred to as heterotypical variants. There are also homotypical variants, which have all the six layers (Standring 2008). Some recent evidences support the association of specific genes with the neurons of specific layers as well as their progenitors (Molyneaux et al. 2007).

Cerebellar Cortex

The cerebellum is the lower, rearmost part of the entire brain. Eighty percent of the total neurons of the brain are located in the cerebellum (Roostaei et al. 2014). The cerebellum has a similar layered microstructure to the cerebrum. The outer layer or cerebellar cortex is gray matter composed of nerve cell bodies and their dendrites. The distinct layers of the cerebellar cortex, from outside to inward are the molecular, Purkinje, and granule cell layer (Carter 2014). Cerebellar cortex receives excitatory inputs through two routes (Roostaei et al. 2014), which are:

1. *Climbing fibers*: These are olivocerebellar fibers which synapse directly on Purkinje cells.
2. *Mossy fibers*: They connect to Purkinje neurons via granular neurons.

The deep cerebellar nuclei (globose, emboliform, fastigial, and dentate nuclei) are connected with the collaterals arising from climbing and mossy fibers (Roostaei et al. 2014). The cerebellar cortex also contains inhibitory neurons called stellate cells, basket cells, and Golgi cells (Standring 2008).

Cerebellar neuronal integrity is responsible for coordination, balance, and execution of movements. Cerebellum exerts certain non-motor functions like cognitive control and affective regulation (Roostaei et al. 2014).

Conduction Velocity

The hallmark feature of nerve cell is its excitability. The various stimuli to which neurons respond include electrical, chemical, and mechanical stimuli. In response to these stimuli, two types of physiochemical changes are produced. These are:

1. Local potential which are non-propagated.
2. Action potential which are propagated.

Action potential is the main mode of interaction within the nervous system. It is produced due to movement of ions across the cell membrane. This impulse is conducted along the axon in an active and self-propagating manner and at a constant amplitude and velocity. This velocity is known as conduction velocity (Barret et al. 2012). Conduction velocity is also discussed in the context of other excitable tissues like muscle fibers; however we limited our discussion to neurons.

Factors Affecting Conduction Velocity

Action potentials travel down neuronal axons in an ion cascade. Larger diameter axons are able to send signals faster. This is because there is less resistance facing the ion flow. Therefore, conduction velocity is directly proportional to the diameter of nerve fibers. Myelination also increases conduction velocity. The spaces between the myelin sheaths have been traditionally called as the nodes of Ranvier. Myelin does the job of insulation and hence the current flow through it is almost absent. Therefore, in myelinated axons, depolarization takes in such a manner that it skips from one node of Ranvier to the next. This “jumping” of depolarization from node to node is called *saltatory conduction*. It is a swift process that allows myelinated axons to conduct up to 50 times faster than the fastest unmyelinated fibers.

Effects of other factors like age, gender, and temperature on conduction velocity have been studied (Stetson et al. 1992). Nerve conduction

velocity decreases with age due to decrease in number of nerve fibers, reduction in fiber diameter, and changes in the fiber membrane. Conduction velocity also decreases with decrease in temperature as cooling is thought to affect muscle and nerve membrane function, particularly the sodium ion channel. Studies have shown males have faster nerve conduction velocity than females, probably due to their faster increase of white matter in the brain during adolescence (Stetson et al. 1992).

Conduction Velocity: Implications

The cerebral cortex with its distinct organization of cortical neurons which is responsible for unique cognitive function is a basic requirement for intelligence. For a given brain design, the mean cortical nerve conduction velocity can affect the speed of information processing and, in turn, the level of intelligence. This is so because information can only be transferred from one cortical region to another along axons and across synapses. Therefore people with higher IQ, faster processing of information, and ability to analyze complex tasks may possibly have faster neural conduction velocity (Reed and Jensen 1992; Roth and Dicke 2005). Reaction time is an important determinant of processing speed. Conduction velocity also determines the reaction time. Faster conduction velocity reduces the reaction time (Vernon and Mori 1992). It has certain health implications, like individuals with mental illnesses and substance intoxication often have increased reaction times, which affects their cognitive performance, which can be traced back to impairment of conduction velocity due to the disease process.

Axons can be affected by a host of pathological conditions, most of which cause delay in conduction and ultimately to conduction block. Demyelination which occurs in multifocal manner affecting multiple tracts within CNS is seen in disorders such as multiple sclerosis. Though these diseases may typically cause

motor or sensory deficits, it may also cause cognitive dysfunctions seen in psychiatric conditions (Barret et al. 2012). Conduction velocities are adversely affected in peripheral neuropathy (Manganelli et al. 2016). Derangements in conduction velocity can be an early indicator for peripheral neuropathies (Kiziltan et al. 2007). Demyelinating neuropathies can be detected earlier and hence can be prevented from progression by screening conduction velocities.

Conclusion

Evidences support that density of cortical neurons and conduction velocity determine the level of intelligence of the individual (Roth and Dicke 2005). In the process of evolution, it was observed that the density of cortical neurons is higher in higher primates like humans, which makes humans the most intelligent among animals. Cortical neuronal integrity and conduction velocity are responsible for the optimal functioning of the brain. Mental well-being is determined by the cortical neuronal integrity and conduction velocity.

Definition and Synonyms of Cortisol

Once in a “stressed” state, an individual will release a hormone called “cortisol.” Staufenbiel, Penninx, Spijker, Elzinga, and van Rossum describe cortisol as a glucocorticoid hormone. They define it as a regulator for many processes, such as: “fat and glucose metabolism, blood pressure, and inflammatory and immune responses” (2013, p. 1221). Generally, cortisol “awakens” the body to respond to an outside stimulus. Cortisol affects many systems of the body to put it into an alert state. One may feel an increased heart rate and respiration, muscle tension, and increased awareness to happenings around. Cortisol can stay at an increased level or can decrease to a baseline, depending on what the body senses. Any type of stressor can signal cortisol. An upcoming exam for a college student, a chronic illness, or excitement right before going on a roller coaster can trigger the release of cortisol, increasing an individual’s alertness.

Introduction

When an individual becomes “stressed,” the entire body reacts. A particular hormone, cortisol, is one of the many hormones that is released and utilized during that time. Cortisol can affect the body to aid in responding to that stressor. From sleep patterns to blood pressure, cortisol triggers the body to aid in preparedness.

How Cortisol Is Released

According to Chrousos (2009), change is detected by the peripheral nervous system and then within the central nervous system. Once within the brain, the hypothalamic-pituitary-adrenal axis, or HPA loop, is activated, and norepinephrine and epinephrine are released. Chrousos additionally mentions how stress activates the amygdala, nucleus accumbens, and the hippocampus. After the hormones are released, the hypothalamus is activated, which begins the loop. The hypothalamus signals the pituitary, which sends a signal to the adrenal glands, which release the cortisol into the bloodstream. Cortisol is released throughout the body and found “bound” and “unbound” or “free” (Lee et al. 2015). Cortisol is found in the bloodstream, but it can be released through urine and hair, which is how it is typically tested (Lee et al. 2015).

Effects on Immediate Alertness

Cortisol sets the body into a state which affects many bodily functions. It provides the key to help the body respond to whatever stimuli that was received from the peripheral nervous system. Each effect of this reaction plays a role in enhancing an individual’s appropriate response.

Effects on Arousal

Cortisol typically coincides with the circadian rhythm. Cortisol is normally highest in the morning and decreases throughout the day. When presented with a stimulus, cortisol can increase. Researchers have found that an elevated cortisol level can affect sleep patterns, even after cortisol has decreased. Glucocorticoids typically have an “excitatory” effect on the amygdala, prefrontal cortex, and hippocampus. This effect not only affects sleep patterns but also emotion and memory (Russo et al. 2013). Decreasing mechanisms that lower or “inhibit” cortisol may change sleeping patterns. Chrousos explains,

“Interestingly, sleep loss is also associated with elevated level of circulating IL6 in spite of the reduced stimulatory effect of catecholamines on IL6 secretion; this change possibly results from the currently decreased cortisol-mediated inhibition” (2009, p. 376). Commonly, an individual often feels less lethargic when cortisol is present.

Researchers have found that certain types of memory and emotion are affected by cortisol. Elzinga, Bakker, and Bremner explain in their 2005 study that specific stress exposure affects long-term memory storing and aids in immediate recall too. Another researcher, McEwen, describes a study explaining how emotional memories aid in already increased memory state when cortisol is present (2008).

Effects on Other Systems

Cortisol alerts many of the body’s other systems. An individual’s metabolism changes with increased heart rate and blood pressure along with gluconeogenesis and hepatic glucose secretion (i.e., producing sugar within the bloodstream). The body requires more energy during those states, so more sugar is released. Most thyroid and reproductive hormones have decreased, because energy is required elsewhere to keep one alert. The same is with the gastrointestinal function. It, too, decreases so energy can be used to attend to the stressor. An individual’s immune system is affected by cortisol as well. Depending on how long a stressor is present and the condition that an individual’s body is in, immunity could be enhanced or decreased (Chrousos 2009).

Conclusion

One hormone ignites an array of bodily processes that not only affect the neurological system but also the endocrine and many other systems. With cortisol’s presence, an individual is more prepared for stressors. Without it, one would respond to outside stimuli at an inappropriate state.

Birds

Definition

Corvids are birds within the taxonomic family Corvidae and include crows, ravens, magpies, jays, and other species.

Introduction

The family of birds known as the Corvidae is an expansive family of over 120 species (including crows, ravens, magpies, and jays, among others; Clayton and Emery 2007). Many species within Corvidae are known for their sociality and intelligence (Clayton and Emery 2007; Seed et al. 2009). As such, they are an excellent target for studying the convergent evolution of social behaviors, in contrast to primates and other mammals. One area of social behavior of particular interest is morality; morality is an integral part of being human, yet whether it exists in other animals to the same degree as in humans is contentious.

Morality can be broken down into three levels of study: moral behavior, moral motivation or intent, and moral systems (Allchin 2009). Moral behaviors include altruistic behaviors such as cooperation and helping (regardless of whether this is “true” altruism, reciprocal altruism, or kin selection). Moral motivations include sympathy, empathy, and innate motivations for helping. Moral systems include social systems that enforce cooperation through reward or punishment. There is also the level of moral cognition: being able to

detect the intentions (positive or negative) of others (as either theory of mind or just behavior reading), being able to learn from and react to the behaviors of others (social learning), and being able to keep track the history of the behaviors of group members (reliability).

Reciprocal altruism in particular is considered a hallmark of human behavior, and many moralistic motivations appear to regulate it, such as friendship, dislike, moralistic aggression, gratitude, sympathy, trust, suspicion, and guilt (Trivers 1971). At the level of the cognition involved in reciprocal altruism, fairness and reconciliation are behaviors that are currently of high interest in research of nonhuman animals. Although it is clear that some species of corvids have extremely complex social systems, the degree to which they have morality is less obvious. This entry will cover precursors to morality in corvids, such as their social systems and evidence for cooperation, social learning, and theory of mind.

Social Systems

Corvids span a huge range of social systems, from solitary to social living in groups almost as complex as those found in primates (Clayton and Emery 2007). Morality is essentially a social concept, so the first place to look for moral behaviors in nonhuman animals is in those with the most complex social groups. Clayton and Emery (2007) review some aspects of the sociality of various corvid species. Many of these species engage in what is called *fission-fusion dynamics*, a pattern that is common in primate societies, as well as some bat species, dolphins, elephants, and spotted hyenas (see Aureli et al. 2008, for review). Social groups with fission-fusion dynamics are composed of large groups that break into smaller groups and reform the larger group over time (hours, days, weeks, or months; Aureli et al. 2008). As this is one of the more complex forms of sociality, it is perhaps within these systems that we might expect to find rudiments of morality.

Rooks are perhaps one of the better-studied species with fission-fusion dynamics; rooks breed in extremely large colonies where mated pairs (forming lifelong pair-bonds) claim so-called micro-territories, but they disperse in other times of the year (Clayton and Emery 2007). Juvenile rooks form valuable relationships that mirror the pair-bonds they will form as adults (reviewed in Clayton and Emery (2007)). These relationships, typically between pairs of rooks, are characterized by affiliative behaviors (food sharing, allopreening [grooming each other], supporting each other in social interactions, caching food together, and bill twinning [holding their bills together]). However, affiliative behaviors are also directed at other individuals, and not all juvenile rooks form these pairs (Clayton and Emery 2007). Aggression never occurs between pairs, although rooks do direct aggression toward other rooks (including physical aggression, chasing, and displacing other rooks from perches), and pairs are much more likely to help each other (as opposed to others) during aggressive interactions (Clayton and Emery 2007). Rooks gain group benefits from being in pairs, beyond just food sharing; rooks in pairs increase their dominance within the group over time compared to non-paired rooks (Clayton and Emery 2007). In addition, affiliative behaviors are often part of a direct exchange, including giving and receiving food but also food for preening and vice versa, as well as bill twining and social support, indicating that these are reciprocal relationships (Clayton and Emery 2007).

Jackdaws, yellow-billed magpies, and pinyon jays also breed in pairs while nesting in colonies (Clayton and Emery 2007). Jackdaws in particular share many social variables with rooks. They form lifelong pair-bonds, and they share many of the same affiliative behaviors between partners that rooks do, and although they associate only with their partner during the breeding season, they live in large flocks the rest of the year, unlike rooks (Clayton and Emery 2007).

Pinyon jay groups are strongly characterized by fission-fusion dynamics, as individuals will not

only form subgroups within colonies but also move between different colonies altogether (Clayton and Emery 2007). Young pinyon jays live in crèches with other offspring where they are cared for by their own parents but also subsets of adults that are unrelated to them (Clayton and Emery 2007). This social complexity is accompanied by strong social cognition: pinyon jays are better at tracking multiple dyadic relationships more rapidly and more accurately than less-social western scrub-jays (reviewed in Clayton and Emery (2007)). These dyadic relationships were presented arbitrarily (as colored squares in a hierarchy) or socially (by observing interactions between other pinyon jays). A series of colors (or a group of jays) formed a hierarchy, and pinyon jays were able to infer and correctly respond to that hierarchy just from experience with the pairs (i.e., red beats blue, blue beats yellow; therefore, red should also beat yellow, called transitive inference). Thus, pinyon jays show high social complexity and awareness of social relationships (see Clayton and Emery (2007)).

Jungle crows do not live in colonies and instead defend territories in pairs. However, this behavior is not ubiquitous. In nonbreeding seasons, they will defend their territory during the day and roost communally off the territory (in breeding season, pairs remain at the nest all day and night), also reflecting fission-fusion social dynamics (Izawa and Watanabe 2008). Despite this flexible social structure, jungle crows form linear, stable dominance hierarchies determined by sex and aggressiveness, at least in captive populations (Izawa and Watanabe 2008). These hierarchies, once established, are maintained, implying long-term individual recognition of conspecifics (Izawa and Watanabe 2008). Long-term recognition has been confirmed by two newer studies: jungle crows recognize individual calls of different types (Kondo et al. 2010), and they match calls with visual presence of an individual (Kondo et al. 2012).

American crows also form lifelong pair-bonds and defend year-round territories in groups, but like jungle crows, some individuals form large

communal roosts for part of the year (Caccamise et al. 1997). American crows breed cooperatively, which means that they get assistance from related and unrelated individuals (helpers at the nest) also living within the territory. These helpers at the nest feed nestlings (Caffrey 1999). This behavior can be advantageous to the helpers in three different ways (Wiley and Rabenold 1984). First, there may be direct survival or reproductive benefits of staying, indirect benefits of increasing sibling survival, and delayed direct benefits of increasing later chances for acquiring a territory or mate (Wiley and Rabenold 1984). One interesting finding with regard to American crow sociality is their ability to form long-lasting memories of threatening humans (Marzluff et al. 2010). In addition, this learning is socially transmitted, both horizontally (to crows that observe a crow scolding a threatening human) and vertically (from parents to offspring; Cornell et al. 2012).

Carrion crows, Florida scrub-jays, and Mexican jays defend territories with a mate year-round (Clayton and Emery 2007). These species do not form colonies or roosts, but within their territories, they engage in cooperative breeding, like American crows. Carrion crows in particular are well known for their cooperative breeding habits, although they only engage in this behavior in some areas (see Clayton and Emery (2007), for review). Carrion crow, Florida scrub-jay, and Mexican jay territories are often also occupied by undispersed yearlings (adult offspring of the breeding pair) or unrelated immigrants to the territory (Clayton and Emery 2007). These extra occupants are helpers at the nest and assist with feeding nestlings, defending the nest, and detecting predators (Clayton and Emery 2007). Carrion crows also show attentiveness to traits of other crows and discriminate between reliable and unreliable conspecifics in terms of responses to alarm calls (Wascher et al. 2015). In addition, they can discriminate between familiar and unfamiliar human and jackdaw sounds, although the authors did not test their recognition of conspecific calls (Wascher et al. 2012).

Ravens, black-billed magpies, and Clark's nutcrackers form pair-bonds and nest inside their own large territories, without forming colonies

or engaging in cooperative breeding (Clayton and Emery 2007). However, juvenile ravens, before claiming a territory, live in larger groups and will aggregate at areas of surplus food (Clayton and Emery 2007). These groups do show fission-fusion dynamics (Clayton and Emery 2007). Juvenile ravens will form large flocks for feeding, roosting, and eating, but then break off into smaller and looser aggregations for other portions of the day, in which affiliative behaviors are common between pairs (Clayton and Emery 2007). Despite the tendency of breeding adults to occupy their own territory, this shows that ravens may also have complex social habits. Indeed, ravens have very good social memory: they can differentiate between individual ravens who have observed (or not observed) them hiding food (Clayton and Emery 2007). Ravens also differentiate between the calls of different ravens, including familiar and unfamiliar calls (Boeckle et al. 2012). They also have long-term memory about the calls of ravens that they have affiliated with and discriminate between not only familiar and unfamiliar calls but also calls from ravens with differing relationship qualities, even when the calls are from ravens they have not interacted with in years (Boeckle and Bugnyar 2012).

Like other corvids, New Caledonian crows form lifelong pair-bonds. However, they are less social than even other crows as they tend to live in small family groups with no unrelated individuals, and they do not defend territories (Holzhaider et al. 2011). While young crows stay with their parents for up to 20 months, they do not help with younger offspring (Holzhaider et al. 2011). New Caledonian crows are one species of corvid that is highly studied, but usually for their tool use-related cognition, rather than social cognition (see Holzhaider et al. (2011) for review). However, their tool-using behaviors are linked with interesting social cognition, such as social learning.

Social Learning

Social learning is the ability to enhance individual learning via observation of a conspecific. This can

result from mere stimulus enhancement (seeing a conspecific manipulate an object encourages the individual to manipulate that object as well), emulation (copying of the end result without copying the steps to get there), or imitation (copying the steps and the end result of a conspecific's actions; Whiten 2000). The ability to engage in social learning involves the ability to closely attend to the actions of others; although this is not a moral behavior in itself, it may be a precursor to more complex abilities that can involve moral-mental processes or behaviors.

Many corvid species demonstrate social learning. Rooks choose to forage near other rooks, and the roosts of ravens and hooded crows allow corvids to communicate the location of food sources to each other (see Seed et al. (2009) for review). New Caledonian crows, which use tools in the wild, appear to use social learning to learn how to make and use tools. Although much of their tool-using habits are genetically determined and emerge during development even without social influence, young crows prefer to use tools they have seen being manipulated, which enhances learning (Seed et al. 2009). In addition, the distribution of tool-making techniques across groups of New Caledonian crows suggests social transmission of these techniques (Seed et al. 2009).

Corvids have also been assessed for social learning in laboratory settings. Florida scrub-jays can learn foraging techniques via observation (Seed et al. 2009). Both Pinyon jays and Clark's nutcrackers were allowed to observe conspecifics solving a motor task (pecking a lid off a container to find food) and a discrimination task (learning which of two containers with different colored lids held food; Templeton et al. 1999). Pinyon jays learned both tasks faster when allowed to observe conspecifics solving these tasks, but Clark's nutcrackers did not seem to benefit from observation; as Pinyon jays are more social than Clark's nutcracker, this suggests an effect of living in large social groups on developing the ability to learn socially (Templeton et al. 1999). Jungle crows also show sophisticated social learning; they will copy techniques used by demonstrators to gain food from a puzzle box though this learning

appears limited to dominant individuals (Izawa and Watanabe 2011).

Cooperation

Cooperation is widespread in corvids. Carrion crows, Florida scrub-jays, Mexican jays, and other corvids engage in cooperative breeding, which can involve provisioning of (sometimes unrelated) offspring and cooperative territory defense from both predators and conspecifics (Clayton and Emery 2007). Other forms of cooperation in corvids are less well studied. Rooks, however, have been studied in a cooperative context, and although they can learn cooperative tasks (such as pulling two strings to draw in food), they do not appear to attend to their partner's actions and will pull their string even when the partner is absent (Scheid and Noë 2010). In addition, success at this task is not related to tolerance, as closely affiliated rooks do not perform better than those less closely affiliated (Scheid and Noë 2010). Instead, a bold temperament influences cooperation success; if at least one raven in a dyad is bold, they will succeed at pulling strings to reach food together (Scheid and Noë 2010). This may represent lack of physical knowledge, but could reflect a lesser degree of social knowledge than in species that succeed on this sort of task, like chimpanzees.

Ravens perform better than rooks on the same cooperative task (Massen et al. 2015); they needed no training to learn the task, unlike rooks. In addition, tolerance was an important factor influencing success, unlike rooks and like other species (Massen et al. 2015). But like rooks, the ravens did not appear to understand the necessity of a partner's actions as they pulled the string even when alone and did not always wait for a partner to appear (Massen et al. 2015). In line with ravens' inability to attend to other's actions in a cooperative task, ravens also do not cooperate in food reward distribution tasks (Di Lascio et al. 2013). When given the choice to receive a food reward, or receive a food reward and have food delivered to another raven, ravens did not appear to differentiate between these options. As ravens

do share food with partners in the wild and in captivity, the complexity of this task may have prevented cooperation.

Theory of Mind

Theory of mind is the ability to understand that another animal's behaviors are caused by mental states, such as beliefs and intentions (see Emery and Clayton (2009), for review). Many corvid species show some evidence of theory of mind, but these examples are still highly debated.

The debate around corvid theory of mind centers around food caching; many corvid species (pinyon jays, Mexican jays, scrub-jays, Clark's nutcrackers, ravens, rooks) will cache food for the purpose of eating later, and in response, these species will also pilfer the caches of conspecifics (Emery and Clayton 2009). Because of the risk of a cache being pilfered, those corvids involved in storing food take measures to protect their caches; these cache protection behaviors may result from multiple cognitive abilities, only one of which is theory of mind (Emery and Clayton 2009).

Scrub-jays are probably the best studied with regard to food caching (Emery and Clayton 2009). Scrub-jays with pilfering experience will re-cache food that was originally cached with a conspecific present (Emery and Clayton 2009). The ability to apply their own experiences to the behavior of other jays specifically could suggest the ability to attribute knowledge states (Emery and Clayton 2009). In addition, when observed, scrub-jays will re-cache food where other jays cannot see them, such as in shaded areas, rather than well-lit areas, and areas far or out of sight (behind barriers) from an observer, rather than close or in sight (Emery and Clayton 2009). These behaviors suggest the ability to take the visual perspective of others. Lastly, they can keep track of multiple observers and selectively re-cache food based on which observer watched what food is being cached (Emery and Clayton 2009). Ravens also prefer to cache far away and out of sight of conspecifics, and they will also re-cache food that was originally cached in the presence of another raven (Emery and Clayton 2009). Clark's nutcrackers

also cache less when observed and then later re-cache food that was cached under observation (Clary and Kelly 2011). Eurasian jays also prefer to cache food items out of sight of conspecifics (Legg and Clayton 2014). Overall, corvids show sensitivity to conspecific behaviors when caching food items, although whether this sensitivity demonstrates a theory of mind is still under debate. This sensitivity may be a precursor to moral-mental states, such as empathy.

Conclusion

Corvids have many complex and interesting social systems, some of which involve fission-fusion dynamics, a hallmark of primate societies. They also show some signs of cooperation involving kin selection and possibly reciprocity. However, they show few behaviors that could be classified as moral, and whether they understand mental states is still under debate. Despite this, they show many potential precursors to morality (the aforementioned cooperation and possibly the existence of theory of mind), so this is not a futile area of study for those interested in how morality evolves.

Attachment parenting; Bed-sharing; Mother-infant co-sleeping; Mother-infant proximity; Natural-parenting; Room-sharing

Definition

Co-sleeping refers to any situation in which a committed adult caregiver, usually the mother, sleeps within close proximity to her infant, so both parties can respond to the others' sensory signals, permitting mutual monitoring and regulation.

Introduction

For humans, mother-infant co-sleeping reflects adaptation for intensive parenting. Among mammals, co-sleeping with newborn offspring is universal as infants are born underdeveloped, typically without hair and therefore require mother for thermoregulation and continual nourishment. Social primates derive additional benefits from co-sleeping (i.e., mother-infant, but also group-sleeping with other kin) such as protecting an infant from predation, within-group competitive interactions, and infanticide (Nunn et al. 2009). Co-sleeping for humans in the early stages of infancy allows the mother to provide a suitable environment to promote healthy development, which is important due to the extreme immaturity of infant brain and body at birth. It is important to note, while co-sleeping has adaptive benefits, it is not known how much deviation from the prototypical pattern is possible without harming developmental outcomes, though such information has implication for cultural practices (Schön and Silvén 2007).

Exterogestation and Human Altriciality

Human infants are born remarkably altricial (i.e., underdeveloped), so much so that relative to other primates, the human infant appears incomplete at birth and the first year of life resembles continued gestation outside the womb (i.e., *exterogestation*) in which the unfinished brain and physiological systems (e.g., immune, digestive, thermoregulatory, respiratory, central nervous) require continual contact and feeding to reach their potential (Montagu 1961). Postnatally, the human infant has been characterized as being of a carried, rather than cached, type (e.g., Schön and Silvén 2007).

Carried infants require more frequent feedings due to the composition of breast milk, the hip and leg morphology as well as startle response promotes clinging, the fat distribution is reduced ventrally to allow mother-dependent thermal synchrony, and the infant cries when separated from mother. Maternal cues that indicate presence are soothing to human infants such as constant touch, smell, voice, movement, heartbeat, and warmth. Co-sleeping provides those cues when not being carried, reducing infant distress and potentially providing other benefits. For example, when human infants are born prematurely, kangaroo care is recommended (World Health Organization 2013), in which the infant is secured to the mother's chest in skin-to-skin contact for extended time periods. Kangaroo care provides maternal cues constantly and is associated with stabilization of infant physiology and behavior, regulation of sleep-wake cycles providing more alert time and more restful sleep, reduction of biological indices of stress, sensitivity and bonding between mother and infant, and increases the rate of neuromaturation (Feldman 2004). Of particular interest, is the synchrony of mother-infant sleep-wakefulness patterns, which is associated with reduced infant mortality (McKenna et al. 1990) and increases temporally matched interactive synchrony of care-solicitation and care-provision, which may affect parent-child attachment.

Social Development and Attachment

The evolutionary pressures that resulted in humans birthing such an altricial infant are debated, but the result is an infant with a unique developmental pattern, such that elaborate communication and social skills develop before physical capabilities (Flinn and Ward 2005). Beginning at birth, mother-infant interactive synchrony begins (Feldman 2007). The reliability and consistency of maternal response provides information to the infant about acceptance, cooperation, and availability. The sensitivity of the parental responses play an important role in organizing parent-infant attachment, such that secure

attachment results from the caregivers ability to perceive accurately and respond contingently to infant needs, providing a sense of security about the world (Ainsworth 1979). The security of attachment to the primary care provider becomes generalized and affects the developing humans' expectations, attributions, and responses to social situations and the world in general (Bowlby 1969). Co-sleeping during the nascent stages of attachment organization is likely important in promoting an attachment style characterized by trust and security, as opposed to exposing the infant to nocturnal maternal deprivation which introduces long periods of nonresponsive care provisioning.

Cultural Practices in Human Parenting

In modern humans, parenting practices are heavily influenced by culturally prescribed norms. In the case of infant sleeping location, cultural practices may be maladaptive. Biological evolution and thus basic infant needs are stable relative to the rapidity of cultural innovation (Schön and Silvéen 2007). In western-industrialized nations, cultural innovations facilitate parenting in an environment that differs from that of human evolutionary adaptedness. For example, the use of a breastmilk substitute allows mothers to remain in the workforce, but at the cost of optimal nutrition, bonding, and acquired immune defenses. In western cultures it has become commonplace to not only feed an infant formula but to sleep them away from their mother in a separate room, due to a separate room available and a cultural value of independence. Sleeping an infant in a separate room is associated with increased risk of infant mortality, as the mother is unable to monitor the infant. The American Academy of Pediatrics (AAP; Jones 2012) proposes to avoid increased risk of infant mortality associated with sleeping an infant in a separate room, the infant should sleep in the same room, but not in the same bed (i.e., room-sharing), as opposed to bed-sharing which is likely what humans evolved doing and is practiced in most cultures around the world. The AAP proposes the modern sleep environment may contribute to infant

suffocation and therefore caution should be taken. Ultimately, it is not known how much deviance from the evolved prototype is possible without compromising infant and parental well-being. Room-sharing or sleeping the infant in a separate room does not provide the same sensory cues (e.g., smell, movement, sound, warmth) that allow the mother's body to scaffold the infants development.

Conclusion

In the grander scheme of mammals which are born underdeveloped, and complete development externally being nourished by mother's milk, it is not surprising that for human mothers and infants, sleeping in close proximity is comfortable, safe, and beneficial. The length of time needed co-sleeping to meet the physical, social, and emotional needs of the infant is not clear, though during the early months skin-to-skin contact is beneficial and promotes secure attachment. Changes in cultural childrearing practices are much more rapid than biological evolutionary changes and as such may not be adaptive. Ultimately, the human infant is born more altricially than any other social primate, as such it is more extensively affected by its developmental environment. Most important to a human infant is the social environment, his approach to which is anchored by the security of early attachments. More research is need to understand the implications of variations in childrearing practices to ensure that infant needs are met in continuously changing and adapting human societies. Taking an adaptationists approach, an increasing number of parents are engaging in *instinctive parenting* (Schön and Silvéen 2007), assuming that any deviation from an evolved prototype has potential for harm.

Definition

Products applied to the body to enhance, change, or improve appearance

Introduction

A cursory glimpse at any television show or magazine depicting women will instantly cue the observer to the role or at least existence of cosmetics in the perception of female attractiveness. Women on TV, movies, in magazines are often covered in various cosmetics. Eyeliner and mascara make eyes look bigger, lipstick calls attention to the size and shape of a woman's mouth, foundation or face powder cover blemishes on the skin – all traits that are found attractive (larger eyes, red lips, clear skin). A somewhat recent beauty fad is “contouring” and “highlighting” the skin to accentuate specific parts of the face. Interestingly, some individuals use this technique to manipulate the shape of one's features. For example, by shading/contouring along the sides of the nose and adding a strong highlight down the center of the nose, it can create a modified nose shape without all the risks (and recovery) of surgery. From an evolutionary perspective, this is considered a form of *dishonest signaling*.

The Nature of Signaling

Sexual selection is comprised of two types of signals: honest and dishonest. Honest signals are when a specific trait reliably relates to underlying fitness and fertility, while dishonest signals may improve one's appearance and therefore mate value, but it is not linked to a person's reproductive potential (i.e., genetic code). Cosmetics fall under the category of dishonest signals – they may play up features found attractive due to their links to fertility or reproductive potential, but a bit of powder and/or ink cannot increase fecundity. Cosmetics can also be considered an *extended phenotype* (Dawkins 1999; Etcoff et al. 2011). In nature, animals use various techniques to bolster their position in the mating market, and in humans, cosmetics play the same role. By drawing attention to favorable characteristics (eyes, lips), it exaggerates important subtleties in sexual dimorphism that are often valued as indicators of fitness.

Facial attractiveness is often linked to symmetry (an overall cue to fitness), but it can also be broken down by individual parts.

Skin: Smooth, unblemished skin is a cue to a lack of mutations and overall fitness. While clear, evenly colored skin is an indication of health, sallow colored skin is often typical in those with diseases. Additionally, the presence of acne (in an adult) is usually indicative of an underlying hormone imbalance.

Eyes: Large, neotenous, clear eyes are a cue to fitness and are considered attractive, while “cloudy” irises and/or discoloration of the sclera is due to underlying health issues.

Lips: Full lips are considered attractive, and it has been suggested that there may be some similarities between the lips and the shape/color of the vagina.

Facial Shape: High, prominent cheekbones and a small lower face are considered attractive and are linked to higher levels of estrogen.

Conclusion

Cosmetics enhance signaling cues – they enhance various features while downplaying others. From an evolutionary perspective, cosmetics are dishonest signals of fitness but are good at the job they do – making naturally attractive features more apparent. While subtle use of cosmetics are typically used to highlight various features (e.g., mascara darkens and elongates eyelashes), other applications (like the layering of concealer to change the shape of the face) are more drastic in nature. All forms of cosmetics are considered dishonest signaling, yet the degree of dishonesty is dependent on the application.

[Mate retention](#); [Domestic violence](#)

Definition

Cost-inflicting behaviors include those behaviors that cause physical or psychological harm to an individual and/or reduce an individual's access or perceived access to resources.

Costs of Intimate Relationship Development

Developing and maintaining an intimate relationship require the investment of resources, in terms of time, energy, finances, emotional commitment, and so on. If the benefits gained from being involved in an intimate relationship outweigh the costs of developing and maintaining that relationship, then the result is a net gain. If the costs

outweigh the benefits, on the other hand, the result is a net loss.

Males and females tend to bring different investments into a relationship and so may incur different costs for committing to such a relationship (Miller 2011). Males, for instance, are more likely to make investments of material resources. In effect, males can buy their way into a long-term relationship by demonstrating not only that they have money – or at least the potential to acquire money – but also that they are willing to use that money and the things that it can buy toward the benefit of a romantic partner and her offspring. Unlike males, the resource that females are most likely to invest in a romantic relationship is themselves. Rather than material resources, males are more likely to prefer that their female partners bring to the relationship sexual access and indicators of reproductive capacity (e.g., postpubertal youth, a low waist-to-hip ratio, facial symmetry, and attractiveness). In short, within the context of long-term intimate relationships, males' material resources are traded for access to females' embodiment of reproductive capability (Buss 1989). Of course, males and females provide many different benefits to one another in the context of an intimate relationship, and in a modern industrialized context, the roles of *provider* and *primary caregiver* are not resolutely sex specific. However, over the course of human evolutionary history, by virtue of sex differences in reproductive biology and all of the downstream consequences of those differences (Trivers 1972), males have been responsible for the heft of material resource investment, and females have been responsible for the majority of reproductive resources.

Typically, the investments males and females make toward the development and maintenance of an intimate relationship are given willingly. Males provide their partners with access to their material resources with the confidence that their female partners cooperatively will provide them with reproductive resources and vice versa. However, while both males and females can benefit from their investment in a long-term relationship, they

also both can potentially benefit from failing to provide a valuable return on their partners' investments, thus tipping the benefits in their favor and the costs toward their partners. In the context of a long-term relationship, many of these costs are inflicted on a partner via relationship defection.

Costs and Benefits of Relationship Defection

There are two main types of relationship defection, and both carry with them potential benefits for the defector and costs for the partner. The costs of a partner's short-term defection from a relationship, the type of defection often dubbed an infidelity, are most evident for male victims of a female's defection. Should a female engage in a sexual infidelity with a rival male, she could conceive offspring to which her long-term partner is genetically unrelated yet in which her long-term partner provides investments. That is, he could be cuckolded (Platek and Shackelford 2006). Cuckoldry, or the unwitting investment in genetically unrelated offspring, is evolutionarily devastating for males, in that it involves investing his finite resources toward the survival of a rival male's offspring while failing to ensure the survival of his own genetic line. The benefit to a female for subjecting her long-term partner to the risk of this cost is that she may gain high-quality genetic resources from her short-term partner. This benefit to females is evidenced in the fact that the risk of female short-term defection from a relationship seems to be highest at ovulation, which is precisely the time when that defection would inflict the most cost on her partner (Pillsworth and Haselton 2006).

Females, of course, cannot be cuckolded. But that does not mean that they incur no costs from a male long-term partner's short-term defection. A male who has engaged in an infidelity necessarily has expended at least some effort – in terms of time, attention, or material resources – in securing a partner with whom to engage in that infidelity, effort which otherwise could have

been allocated toward his long-term partner and her offspring. In effect, his short-term defection has cost her access to some of his resources. Additionally, both males and females who have been the victim of a partner's short-term defection face the additional risk that the short-term defection will be translated into a long-term defection.

Short-term defections from a long-term relationship are sometimes used as a method of "trading up." That is, if the benefit of being in a relationship with the new partner outweighs the cost of leaving the previous partner, then one may be likely to dissolve the previous relationship. When a long-term relationship dissolves, each member of that relationship loses whatever investment has been made into that relationship. In short, they incur the cost of having invested in that relationship without being able to receive the benefits that relationship could have provided.

In order to prevent incurring the costs of a partner's defection from the relationship, individuals may engage in mate retention behaviors. In short, mate retention behaviors include all of those things that an individual may do in order to encourage a partner's continued investment in the current relationship. Some of these behaviors function by enticing a partner's fidelity via the provision of benefits. These benefits might include gifts, compliments, or any other thing a person may appreciate receiving. Other mate retention behaviors function by punishing or threatening to punish a partner's defection from the relationship. These are called cost-inflicting mate retention behaviors (Shackelford and Buss 2000).

Cost-Inflicting Mate Retention

Cost-inflicting mate retention behaviors can take many forms. For example, a person might inflict financial hardship on his partner by restricting access to money or other material resources on which she relies. He also may attempt to restrict his partner's access to social resources by insisting

that she spend all of her time with him or otherwise preventing her from having meaningful contact with other family members or friends. In other cases, an individual may target his behaviors toward rivals who might otherwise entice a partner away from the current relationship. This could include anything from convincing the potential rival that the partner is in some way damaged and so not worth having to physically fighting the potential rival for appearing interested in one's partner.

In the examples above, an individual is attempting to maintain a partner's investment in the current relationship by removing opportunities to defect or otherwise establishing barriers to defection. However, another approach would be to lower a partner's *perceived* ability to defect from the relationship. For instance, successfully convincing a partner that she is of such low value that no other partner would ever have her and that she would be incapable of surviving in the world on her own serves the same purpose as actually removing her opportunities to defect. There would be no need to actually remove opportunities for defection if one has successfully convinced a partner that such opportunities do not exist.

The restriction of a partner's access to material and social resources, whether that restriction is actual or perceptual, is costly to that partner. The cost inflicted on a partner functions to protect oneself from incurring the costs of a partner's defection from the relationship. However, not everyone engages in these cost-inflicting mate retention behaviors with equal frequency.

Individual Differences

The use of cost-inflicting mate retention strategies is moderated by a variety of individual differences. In general, mate retention is positively related to one's partner's mate value, such that individuals with higher mate value are more likely to engage in mate retention behaviors (Buss and Shackelford 1997). In other words, a person with a valuable partner

is likely to want to keep that partner and so will engage in more behaviors that function to maintain that partner's investment in the current relationship. This is likely because the cost of a partner's defection from the relationship is greater when the partner could not be replaced easily. Similarly, the likelihood of the use of mate retention behaviors is increased when the risk of relationship defection is highest (Starratt et al. 2007).

In circumstances such as these, when one may be motivated to engage in mate retention behaviors, there are individual differences in the extent to which one chooses a cost-inflicting strategy. Specifically, individuals who are lower on the mate value spectrum are more likely than their higher-value cohorts to use cost-inflicting mate retention strategies (Miner et al. 2009). Generally, a person who is considered "high value" is one who has many of those traits that are prized by those who are seeking a mate, traits such as kindness, intelligence, attractiveness, and, at least for males, access to resources. A person with these high-value traits may have several advantages over lower-value rivals, including the ability to afford the investment it takes to engage in benefit-provisioning mate retention.

Enticing a partner into maintaining fidelity to the current relationship by providing that partner with benefits typically requires some manner of up-front investment. For instance, purchasing a gift requires the investment of financial resources. Providing social or emotional support, on the other hand, involves the investment of one's time, kindness, and potentially intellectual prowess. A person of low mate value is less likely to have any of these resources to invest – or may have the resources but is less likely to be inclined to use those resources toward the benefit of another, as may be the case for a partner with financial resources but without kindness or other such positive personality characteristics. Such low-value partners, though, still may have a need to engage in mate retention. Consequently, these individuals may be more likely to engage in those mate retention strategies that involve inflicting costs on their partners.

Conclusion

The development and maintenance of intimate relationships require the investment of a variety of resources. Should an individual's partner defect from that relationship, even briefly, one risks losing that investment, thus incurring potentially substantial costs. In order to prevent incurring such costs oneself, an individual may choose to inflict costs on his or her partner in the form of cost-inflicting mate retention behaviors. These behaviors function to maintain a partner's investment in the current relationship by inflicting or threatening to inflict costs for defection. The likelihood of one's engagement in cost-inflicting behaviors is highest under two conditions: (1) when the risk of a costly loss from a partner's defection is greatest and (2) when the individual is either unable or unwilling to maintain a partner's investment in the relationship through the provision of benefits.

Cost of Same-Sex Friendships

Minna Lyons

University of Liverpool, Liverpool, UK

Synonyms

[Affiliative bonds](#); [Associations](#); [Coalitions](#); [Female-female](#); [Male-male](#); [Reproductive costs](#); [Social relationships](#)

Definition

Same-sex friendships are lasting coalitions between individuals who are the same biological sex. Friendships can have substantial fitness costs in terms of time budgets for maintenance, as well as costs associated with violation of rules of reciprocity.

Introduction

Friendships, characterized by long-term affiliative bonds between unrelated individuals, have an

association with evolutionary benefits of increased reproduction and survival. Evolutionary origins of friendships are best explained by reciprocal altruism, where reciprocity is sustained via proximate mechanisms of emotional closeness and high levels of trust. As well as bringing fitness benefits, friendships also have substantial costs connected to the maintenance of the bonds. As opposed to kin relations, the quality of the friendship bond is dependent on the frequency of the contact. Emotional closeness between unrelated individuals can evaporate over time if the contact with the friend is not maintained regularly (Roberts and Dunbar 2011a), which can result in dissolution of the friendship. The costs and benefits of friendships are different across the life course of the individuals. In this chapter, I will be focusing on the costs of friendships in adults of reproductive age. I will discuss this in terms of energetic costs (i.e., social time budgets), cost associated with violation of reciprocity (i.e., exploitative friendships), and intra-sexual competition and mate poaching.

Maintenance Costs

In order to meet the requirements of reciprocity, friendships have higher maintenance costs than kinships. Social networks are costly in terms of allocation of time budgets; energy allocated in one friendship limits the time available for maintaining other friendships. Indeed, close friendships are characterized by more frequent communication and contact (Roberts and Dunbar 2011b), which can take up a large part of an individuals' social time budget. Further, the costs of maintenance can differ as a function of the sex of the individual.

On average, women have fewer but closer friends in their networks than men do, and these friendships are often nurtured with intensity and intimacy. Women's friendships take more energy to maintain, and friendship conflict and dissolution in women are often caused by lack of care in the relationship by one of the parties (Dunbar and Machin 2014). The intimate same-sex friendship in women is likely to have an association with ancestral patrilocality (the propensity of males to

stay and females to migrate from natal groups when reaching maturity). Establishing non-kin-based close support networks was crucial for ancestral female fitness, which could be reflected in the high cost of maintenance. Ancestral males, in turn, could rely on the support of genetically related individuals, and did not require the costly time allocation in order to maintain the support network. Indeed, friendship networks of modern men are characterized by weaker ties and larger, activity-based groups, whereas modern women have fewer same-sex allies, but the relationships are more intimate and supportive (see David-Barrett et al. 2015, for further references and an interesting study on social media profile pictures).

Conflict, Competition, and Betrayal

Same-sex friendships bear substantial costs when the rules of reciprocation are violated. In some cases, friendships can be exploitative, where one person in the dyad gains benefits at the cost of the other person. Conflict in adult same-sex friendships is surprisingly little studied. Researchers suggest that exploitive friendships have a relationship with individual differences in personality. For example, those who are high on trait Machiavellianism use manipulative tactics in friendships (Abell et al. 2016), which could lead to imbalance in the costs and benefits within the friendship dyad.

Friendships can also be competitive, which is associated with dissatisfaction (Singleton and Vacca 2007) and reduced emotional attachment (Brewer et al. 2013). One common feature of competition is intra-sexual competition for mates (Bleske-Rechek and Lighthall 2010). Although friendships can be useful in terms of cooperation in acquiring and retaining mates, they can be costly when there is within-sex competition for the same mates.

Conclusion

Same-sex friendships can be costly because of high energetic requirements (i.e., social time

budgets) and intra-sex competition and rivalry. Overall, friendships are costlier to maintain than kinships and require a larger amount of an individuals' social time budget. Although friends can provide support in terms of mate acquisition and retention, friendships also pose a risk of intra-sexual competition for mates and losing a mate to poaching from a friend.

Definition

A type of analysis that examines the potential costs of a decision compared to the potential benefits of the decision to determine the optimal choice.

Introduction

Every decision has associated costs and benefits to an organism. This is true for business decisions, parenting choices, and all areas in between. Evolutionarily, an organism's main objective is to successfully allocate resources to maximize fitness, and this is the ultimate goal of all decisions in all areas (Buss 1988). However, organisms do not have the resources necessary to maximize fitness in all areas of life and functioning (Ellis et al. 2009). As a result, organisms must make decisions that involve trade-offs: In order to maximize fitness in one area that is more important, resources must be not devoted to some other aspects of fitness. These decisions are dependent on various factors in the organism's environment that influence what is required to maximize fitness. Therefore, to make sense of all the factors that are involved in fitness-maximizing choices, organisms must perform cost-benefit analyses to determine optimal decisions for their individual situations.

Theory of Cost-Benefit Analysis

Cost-benefit analyses are used for many decisions. In order to make an optimal decision, an organism must examine both the costs and the benefits associated with the choices. For example, in many community project decisions, people must examine the monetary and nonmonetary (time, energy, work diverted from other projects) costs to the community and weigh those against both the monetary and nonmonetary benefits to the community in order to determine whether it is worthwhile to complete the project. For instance, if a community wanted to host a food drive, they would first need to calculate the monetary costs of publicity and worker reimbursement. Then, they would add these costs to the nonmonetary costs like the time and energy the workers would invest and the productivity lost by diverting helpers from their usual jobs to this project. Then, they would calculate the benefits to the community members in need of food assistance and the amount of food they are likely to raise. Finally, they would compare these costs against the benefits to decide whether or not to continue with the project. This type of analysis allows the community to make a productive decision and not invest resources in something that will cost more to implement than it would help after its completion. This same type of analysis can apply to all decisions, although the costs and benefits are not always monetary in nature.

The equation for cost-benefit analysis is as follows:

$$\frac{B \cdot Pb}{C \cdot Pc}$$

This equation multiplies the benefits (B ; usually the expected monetary value) by the probability or likelihood of achieving the expected monetary value (Pb), then divides this by the expected cost of the decision (C) multiplied by the probability or likelihood of keeping that cost (Pc). The rule of cost-benefit analysis says that organisms should choose the option with the highest benefit relative

to the cost when making decisions. Cost-benefit analysis has been used in evaluating many different things, including educational programs, various types of therapeutic interventions, and security and safety initiatives (Herman et al. 2015; Kliezt et al. 2010; Reynolds et al. 2011; Stewart and Mueller 2013). Although it is easy to see how this type of analysis applies to modern business decisions, it also plays an important role in evolutionary decision-making.

Application to Evolution

The fundamental evolutionary goal of any organism is optimizing resources, such as energy and its expenditure, to maximize fitness. The same type of cost-benefit analysis that is used in modern business decisions was also used throughout history and can be examined in many situations in ancestral time. For example, cost-benefit analysis can be seen in scenarios involving hunting a particular animal, such as a bison. For this scenario, there are potential costs to the organism including weapons, energy for the hunt, and risk of injury or death. However, potential benefits to the organism also exist, including the large amount of meat, large bones for tools, and the hide for clothes. In an unconscious manner, a cost-benefit analysis can be used to make the choice of whether or not to hunt a bison. Similarly, various costs and benefits can be examined for many evolutionary investments, including parenting, mating behavior, foraging, aggression, altruism, and more.

Natural selection favors the allocation of resources that are optimized over the lifetime across differing ecologies (Ellis et al. 2009). Natural selection prefers this because an adaptable organism is capable of surviving and reproducing in different environments. Across the lifespan, organisms encounter different problems to solve, and each individual organism will have access to different resources. Therefore, the costs and benefits associated with a certain choice differ based on the organism's specific environmental characteristics. For example, aggression has different

costs and benefits in different environmental situations (Georgiev et al. 2013). Life history theory can be used to understand how costs and benefits differ between and within species across different environments.

Life History Theory and Cost-Benefit Analysis

Life history theory can explain how individuals make different cost-benefit decisions within their environments. There are five main evolutionary trade-offs that require cost-benefit decisions to be made about resource allocation: maintenance versus growth, current versus future reproduction, growth versus current reproduction, survival versus current reproduction, and offspring quality versus quantity (Ellis et al. 2009). The environmental characteristics influence what decisions organisms will make within these realms. For example, in an environment with a high mortality rate, each day is unpredictable, and an organism does not know when vital resources can be obtained for survival. In this type of environment, an optimal decision would be to invest in current reproduction and have a large quantity of offspring. Having offspring earlier and more often will be more fitness-maximizing because life expectancy is shorter and the future is uncertain. When examining the costs and the benefits, this strategy has the higher payout in this environment because it increases the chances of survival for an organism's genes. Waiting to have offspring and having only a few are strategies with lower expected payout because the organism or its few offspring may die in a hazardous environment. In a different environment, however, this later strategy may have a higher payout because of the better probability of living to be able to see the future rewards of investments (such as in somatic growth or offspring quality).

An individual's investment in each of these trade-off categories can indicate their specific life history strategy. A slow life history strategy is characterized by decisions to invest resources in

the future, whereas a fast life history strategy is characterized by investing resources to receive benefits as soon as possible. Individuals can vary on this continuum, and their specific life history strategy influences the cost-benefit analysis associated with each of their decisions about resource allocation. Therefore, organisms use cost-benefit analyses within the contexts of their environment and life history strategy in order to make optimal decisions.

Conclusion

Various evolutionary decisions utilize cost-benefit analyses. Life history theory can be related to many areas that require trade-offs, such as the physiology of an organism, mating behavior, parenting, and reward orientations. Furthermore, all the different aspects of an organism's life can only use a portion of the individual's available resources, so an organism's resources must be divided up in a way that will increase fitness. One way to help make these important decisions is to perform a cost-benefit analysis of the current environment. Organisms using both fast and slow life history strategies utilize cost-benefit analyses to determine the most effective use of resources to increase fitness in their current individual environment.

Definition

An advertisement of one's phenotypic quality of cooperativeness, based on individually risky or resource-intensive displays of cooperation and/or selflessness.

In most social psychology traditions, altruism has tended to be examined in terms of the isolated situational factors which give rise to it on the part of individual altruists. Considerations like social norms and conventions, the proximity of the altruist to bystanders and confederates, the influence of rewards, and transient emotional states and much else have variously been identified as some of the major reasons why people tend to behave in an altruistic manner toward others. While examining these factors remains crucial to informing our understanding of the range-of-the-moment, proximal nature of altruism, adopting an evolutionary psychology lens allows us to assess *why* it is, in distal, ultimate terms, that these underlying motives and situational influences came to be so predictive of altruism (McAndrew 2002).

The proliferation of altruism was once a contentious issue by the lights of evolutionary theory. *Prima facie*, the notion that an individual would behaviorally perform in such a way that they incurred a personal cost (often a great one) only to benefit other individuals, was difficult to explain when invoking evolution by natural selection. It was not until Hamilton (1964) advanced the construct of inclusive fitness – through which altruistic behaviors were selected for through the vehicle of shared genes – that evolutionary theorists could employ an overarching framework through which altruism could be understood. In the intervening five decades since Hamilton's theoretical innovation in this space, a number of other theories – some competing and some complementary – have been advanced to provide additional or alternative grounding for the evolutionary rationale of altruism, including reciprocal altruism, competitive altruism, and multilevel-selection theory, among many others (Griskevicius et al. 2007).

Costly signaling theory (CST) is one such framework. CST operates by the principal that altruistic acts are a means through which individual people amass and mobilize social influence within their group and, as a result, increase their long-term reproductive fitness. People that perform altruistic acts self-interestedly fulfill their own individual objectives by publicly

broadcasting – often at great personal cost – instances of the qualities that underpin these acts, and do so in a manner for which the time, resources, risk, and energy inherent in them is apparent to those around them (Fehr and Fischbacher 2003). The reliability of the *signal* being broadcasted is contingent on its *costliness*, such as the case with instances of public generosity. The public provision of goods and services, instances of charity and philanthropy, and so forth, all imply a real and substantial personal cost in terms of what is sacrificed or spent by the altruist in performing the altruistic act. Such acts of altruism are unconditional, inasmuch as they are generally purposed toward assisting people for whom there is no expectation – both normative and practical – of them ever returning the favor in kind (Gintis et al. 2001; Zahavi 1975).

In performing such altruistic acts, CST predicts that the altruist themselves will benefit from developing a reputation for reliability within cooperative relationships and might thus be chosen as a strategic ally, romantic partner, friend, or mentor (Griskevicius et al. 2007). Obversely, it is not only the person broadcasting the costly signal that stands to benefit under such conditions. To the degree that the signal is reliable, those observing it benefit from high fidelity, useful information about the reputation of the altruist, and thus what the beneficial implications are of engaging in any kind of interpersonal relationship with them. In this sense, costly signaling is a reputation maximization mechanism: the more costly the act of altruism to whoever is performing it, the more effectively they themselves can convey their trustworthiness, and the more accurate their trustworthiness can be interpreted and understood by those around them (Jordan et al. 2016).

Experimental studies have demonstrated this phenomenon in action. The act of donating charitably to strangers has been shown to strongly influence the social attitudes of group members toward altruistic confederates. Among extant pre-industrialized societies, including the Ifaluk of Micronesia and Ache of eastern Paraguay, hunters reap substantial social and reputational

benefits from donating most (often all) of their catch to those within their society who have not incurred the palpable risk and onerous physical activity demanded of successful hunting expeditions that they themselves have. Those who lead such hunts, and who *publicly* share the spoils of them, take the opportunity to showcase not only their sense of charity and collective mindedness but their leadership skills and specialized understanding of local fauna; in the process, gaining both an esteemed reputation and the follow-on benefits of preferential access to high-quality mating partners – thus providing an evolutionary fitness calculus for the philanthropic results of their hunting prowess (Barclay 2012; Bird et al. 2001).

In addition to these revealing accounts of CST in pre-industrial cultural settings, additional empirical work (e.g., Bereczkei et al. 2010) has demonstrated a similar dynamic unfolding in modern, industrialized settings. Altruists have been shown to benefit from a payoff in social recognition, reputation, and group popularity when performing acts that were not only costly to the individual but performed publicly in such a way that the costliness of the acts were readily observable to those around them. Moreover, and as would be predicted by CST, the benefits of social recognition that accrue to the altruist increase proportionally with the inherent costs incurred by performing the act, such that the higher the investment made, the greater the commensurate gain in social reputation.

The notion that altruism ought to exist for its “own sake” – that altruism with any kind of self-serving utility function underlying it is ultimately not altruistic in some sharply definitionally demarcated sense – is a normative claim drawn from the most recent reaches of the human experience. *Why* altruism, and the performance of acts so costly to the individual yet so beneficial to others, came to exist at all within the evolved human neuropsychological architecture requires not just motives or situational explanations but a mechanism and an account of adaptive function.

CST, while not the only evolutionary theoretical framework marshaled to provide such an account, provides an explanation of how the costliness inherent in altruistic acts might be offset by the overall reproductive fitness benefits afforded by their public signaling.

Costly Signaling Model of Suicidal Behavior

► Bargaining Model of Suicidal Behavior

Costly Signaling Theory

Francis T. McAndrew
Knox College, Galesburg, IL, USA

Synonyms

Competitive altruism; Handicap principle; Honest signaling

Definition

“Costly signaling theory” proposes that animals (including humans) may send honest signals about desirable personal characteristics and access to resources through costly biological displays, altruism, or other behaviors that would be hard to fake.

Introduction

The existence of altruism was something of an obstacle for early evolutionary theorists, since an organism that engaged in behavior that came at a great personal cost and seemed to solely benefit other individuals appeared difficult for natural selection to explain. It was not until the introduction of the concept of *inclusive fitness*, also known as *kin selection*, by Hamilton in 1964 that evolutionists had a satisfactory theoretical framework for discussing altruism. The concept of kin selection, however, could not account for the many altruistic acts performed for individuals who are not genetic kin. An additional form of altruism, *reciprocal altruism* (Trivers 1971), explained why these important and socially necessary behaviors occur so frequently. Reciprocal altruism occurs when one organism provides a benefit to another organism at a cost to itself because it has received, or is likely to receive, a similar benefit in return from the other organism.

Neither of the aforementioned models of altruism, however, can explain large philanthropic

gifts, heroic self-sacrificial behavior, or handouts to beggars that will never be directly reciprocated. The most useful perspective on such behaviors has come to be known as “costly signaling theory,” which was first introduced by the Israeli biologist Amotz Zahavi in 1975. Costly signaling theory (Bliege Bird and Smith 2005; Grafen 1990; McAndrew 2002; Zahavi 1977) attempted to deal with these types of altruistic acts by proposing that such behaviors are a vehicle for individuals to advertise desirable personal qualities or resources. This may ultimately benefit the altruist by increasing the likelihood that he or she will be chosen as a mate or an ally and it may also be a way of positioning the individual for greater access to resources through direct or indirect reciprocation (Grafen 1990; McAndrew 2002; Nowak and Sigmund 2005; Roberts 1998; Zahavi 1977).

When the altruistic act is performed primarily for the purpose of advertising one’s own altruistic tendencies, it is referred to as *competitive altruism* because the signaler is effectively competing with individuals who are also attempting to establish altruistic reputations in the eyes of others (Barclay and Willer 2007).

The main distinction between competitive altruism and reciprocal altruism is that reciprocal altruism requires that the altruist is reimbursed by individuals who directly benefited from the original altruistic act, whereas costly signaling and competitive altruism can lead to future rewards from individuals who may not have directly benefited from the original act of altruism (Bowles and Gintis 2011).

Costly Signaling as Honest Signaling

The signals that conspecifics transmit to each other are only useful to the recipients of those signals to the extent that a signal communicates honest, reliable information about the sender. For example, a female who responds to misleading or false information about the quality of a mate may end up being saddled with low-quality offspring and a nonsupportive partner, both of which would

significantly impair her reproductive success. Consequently, there has been significant selective pressure to develop strategies for detecting honest signals of quality in others. In such a system, there must be a cost to the sender if a signal is discovered not to be honest (i.e., cheaters will be punished), and there will be a cost to receivers if dishonest signals are not detected (Higham 2014).

The “cost” of a signal to the sender is a reliable way of confirming the honesty of that signal, so costly signaling is very much about truth in advertising. A “low-quality” signaler who attempts to fake a high-quality signal will deplete whatever resources that he may have available, leaving the signaler in such a vulnerable position that the strategy will prove to be counterproductive. Conversely, a high-quality signaler has resources to burn and can easily afford a high-quality signal, so the adaptive benefits will outweigh the costs (Grafen 1990). Hence, costly signaling theory (CST) proposes that individuals often engage in behaviors that are very costly as a way of signaling honest information about themselves.

Smith and Bird (2000) have described the four qualities that a behavior must have to qualify as a costly signal. First, the behavior must be easily observable by others. Second, it must be costly to the actor in resources, energy, or some other significant domain. Third, the signal must be a reliable indicator of some trait or characteristic of the signaler, such as health, intelligence, or access to resources. Finally, the behavior in question must lead to some advantage for the signaler.

The term “handicap principle” has often been used interchangeably with “costly signaling theory.” This reflects the origins of this theory in research on animal communication where it has been established that some animals “handicap” themselves with extremely costly biological features that only individuals in excellent condition can afford to maintain. The brilliant plumage of the peacock’s tail and the impressive antlers of elk are classic (if a bit timeworn) examples of such handicaps. Many researchers no longer think of these terms as synonymous and believe that handicaps are neither necessary nor sufficient for honest signaling but may still be helpful insofar as

they prevent low-quality individuals from sending high-quality signals (Higham 2014).

Philanthropy as Costly Signaling

Public philanthropy is one of the most common costly signals of social status in humans, especially in Western cultures such as the United States. Universities, public television stations, museums, and the arts depend upon it for their very survival. CST suggests that such philanthropy is a conspicuous display of resources that reinforces the status, resources, helpfulness, and all-around quality of the benefactor. After all, if a person can afford to expend a great deal of money, energy, or time in a manner that seems to be irrelevant to his or her selfish interests, then the resources that are being held in reserve must be very great indeed.

This type of competitive altruism may be a way of positioning oneself for access to resources during unforeseen future times of need (Boone 1998), and there is in fact evidence to support the belief that individuals who have a history of being magnanimous are rewarded by others when times get tough. Among the Ache of Paraguay, for example, individuals who shared more than average with others in good times received more food from more people when they were sick or injured than did those who had been less generous (Gurven et al. 2000). Apparently, having everyone owe you for past unselfishness can be a good hedge against future calamities, and costly signaling may be an effective strategy for inducing reciprocal altruism.

Anthropological studies provide numerous examples of exaggerated displays of public generosity. For example, Smith and Bird (2000) described a form of costly signaling among the Meriam, a Melanesian society located on an island off the coast of Australia. Two to 5 years after a death, the family of the deceased puts on an elaborate feast to coincide with the erection of an expensive and showy permanent tombstone. Gifts are given to all guests, along with prodigious amounts of food. Ideally, one of the main courses is turtle meat obtained through a dangerous, time-

consuming turtle hunt. Successful turtle hunting requires careful coordination of effort and great physical agility, strength, and diving abilities because the turtle hunters have to jump from a boat onto moving turtles in open water. The ability to supply many turtles for the funeral feast serves as an honest signal of the physical quality of the males in the family. Everyone is invited to the feast, and no reciprocation of any kind is expected.

Laboratory studies by psychologists have also demonstrated that charitable donations and other acts of kindness are most likely to take place when the behaviors are easily observed and recognized by others (Bereczkei et al. 2010; Haley and Fessler 2005), and van Vugt and Hardy (2010) have even shown that people will make wasteful contributions in “public goods” situations, knowing full well that the contribution will not make a difference, as long as the contribution is publicly observed. The reason that this occurs is because the contribution is primarily a self-presentation strategy designed to increase the contributor’s status and prestige, with other outcomes of the philanthropy being less consequential to the donor.

Some researchers posit that conspicuous displays of philanthropy and benevolence can be triggered by mating motives, possibly as a way of advertising prosocial personality traits valued by prospective mates, and there are data to confirm that males are more likely to display altruism in the presence of attractive members of the opposite sex; the same does not hold true for females (Farrelly et al. 2007; Iredale et al. 2008). Griskevicius et al. (2007) found that mating motives are especially likely to encourage male generosity if the act of benevolence highlights a man’s prestige or his heroic nature.

The evolutionary roots of philanthropy as a costly signal may be found in the tradition of meat sharing by prehistoric hunters. Successful hunters signaled desirable physical qualities such as physical vigor and health, eye-hand coordination, and mastery of weapons, and by sharing meat they could also demonstrate cooperative, prosocial tendencies that would have been highly valued (Gurven et al. 2000).

Risk Taking and Heroism as Costly Signaling

It’s no secret that young men are notorious for engaging in foolish, risky behavior and that most people fear violent behavior by young men more than violent behavior by older men. In fact, the tendency of young men to engage in risky and/or aggressive behavior prompted the Canadian psychologists Margo Wilson and Martin Daly (1985) to give it a name: Young Male Syndrome. The results of the annual “Darwin Awards” competition support their position convincingly. The Darwin Awards feature those individuals who have lost their lives in dramatic fashion during the previous year by taking stupidity to a colossal new level. For the 5-year period from 2010 through 2014, the Darwin Award winners were skewed toward men by a margin of 38 to 5, with two of the five women who made the list getting there by being talked into having sex with men under less than rational circumstances (<http://www.darwinawards.com/>).

Why would this predilection for recklessness have evolved in young men?

For sound evolutionary reasons, younger men find themselves especially concerned with status and dominance. In early human societies, competitive success in early adulthood established a man’s standing in his social group for the rest of his life; it wasn’t possible to simply hit the “reset” button and join another group, so what happened during the teen years mattered a great deal. For this reason, high-risk competition between young males provided an opportunity for “showing off” the abilities needed to acquire resources, exhibit strength, and meet any challenges to one’s status. Consequently, heroic or even recklessly daredevil behavior was rewarded with status and respect – assuming, of course, that the young man survived the ordeal. Anthropologist Kristen Hawkes (1991) has developed the “show-off hypothesis” to explain the well-replicated finding that men in hunter-gatherer societies who are predisposed toward more risky hunting strategies end up with greater sexual access to women (Hill and Hurtado 1996; Smith 2004; Wiessner 2002).

Today, the widespread promotion of sport in our culture undoubtedly developed as a constructive alternative for dealing with the proclivities of young males that evolved in a very different time. In a legally sanctioned gladiatorial arena, young men are able to exhibit the same skills – throwing, clubbing, running, wrestling, tackling, hand-eye coordination – that would have made them successful fighters or hunters in the ancestral environment. Participating in team sports enables athletes to exhibit other qualities such as cooperativeness, loyalty, and planning ability – all of which are hard to fake (Kniffin and Sugiyama 2018).

This proclivity for recklessness may also be relevant to understanding why men are more likely to flout the conventions of polite society than are women (McAndrew 2018). In other words, why are men more disgusting than women?

Much of the time disgusting behavior is also risky behavior. By eating or drinking things that might be contaminated in some way or by risking social ostracism by flouting the rules of your group, you are putting yourself on the line. You are risking serious illness or excommunication from the group, both of which would have been deadly in the brutal prehistoric world of our ancestors. If you can take such risks and survive them, you are signaling to others that you have special qualities. Hence, behaving in a disgusting manner may in fact be a perverse form of costly signaling that demonstrates superior genetic or personal qualities.

Along these lines, a team of anthropologists at UCLA led by Dan Fessler tested what they called the “crazy bastard hypothesis” in a series of studies (Fessler et al. 2014). They gathered data online from thousands of Americans and in person from dozens of individuals in the Fiji Islands. They had people read short scenarios about individuals who engaged in risky, daredevil behavior or in more cautious, risk-averse behavior. They then asked them to make judgments about the characteristics that they thought the person in the story might possess. Among other things, the daredevil was perceived to be taller, stronger, and generally

more physically formidable than the cautious individual. Thus, risky male behavior may not just be about advertising genetic quality, but it may also advertise how one might behave as an adversary or an ally. If one sees a “crazy bastard” who behaves with apparent disregard for his own personal well-being by doing things that would scare ordinary men away, one might definitely end up wanting to have this person as a friend rather than as an enemy. Even though the crazy bastard’s behavior is not overtly aggressive, one can easily imagine the terror of dealing with such a reckless opponent in combat and the comfort that one might have going into battle with that individual as a comrade. Going back to the dawn of recorded human history, one can find rituals (often involving excessive consumption of alcohol) used by warriors to at least temporarily make themselves feel and appear to be formidable crazy bastards as a way of intimidating their enemies and taking the fight out of them before the battle even began.

A form of risky behavior that serves as an especially effective costly signal is physically risky altruistic behavior, which is the very definition of heroism. Evolutionary psychologists believe that even apparently selfless impulses such as true heroism must provide some adaptive advantage for individuals; otherwise, such behaviors would have been strongly selected against, and many studies confirm that people who sacrifice for the group by engaging in physically costly altruistic activities do in fact achieve elevated social status, respect, and recognition as a result of their public selflessness (McAndrew and Perilloux 2012; Willer 2009), especially when the behavior displays courage and physical strength (Farthing 2005; Griskevicius et al. 2007; Kelly and Dunbar 2001; Sylwester and Pawlowski 2011).

For example, on Ifaluk Atoll in Micronesia, males sometimes engage in torch fishing (luring flying fish into nets at night with torches) when other fishing techniques would actually be more efficient. Torch fishing is a difficult, time-intensive activity but also a highly visible activity that serves to advertise a man’s work ethic (Sosis 2000).

Displaying heroism in time of war is another powerful way for young men to acquire rewards from costly signaling, and historical data confirm that the proportion of a population made up of young men is one of the best predictors of when a society is most likely to go to war (Mesquida and Wiener 1996).

A team of European psychologists explored the proposition that war provides an arena for men to compete and impress both their male rivals and females who might be potential mates (Rusch et al. 2015). In one study, they found that 464 American men who had won the Medal of Honor during World War II eventually had more children than other US service men who had not been so heroically distinguished. This is consistent with the idea that heroism gets rewarded with greater reproductive success.

In a second study, 92 women rated the sexual attractiveness of men who had behaved heroically in war as being higher than that of soldiers who had served but not been identified as heroes. Tellingly, women did not show this increased attraction toward men who had behaved heroically in sports or business situations. A third study revealed that behaving heroically in war does not increase the attractiveness of female war heroes to men. In summary, heroism in time of war is sexier than any other kind of heroism but only for men. Similarly, enhanced access to females has been documented for males who join violent street gangs (Palmer and Tilley 1995).

Therefore, while there are certainly many examples of women behaving heroically, physically risky, self-sacrificial heroism is commonly perceived to be a stereotypically male behavior (Griskevicius et al. 2007; Iredale and Van Vugt 2009; Lyons 2005). If self-sacrificial altruistic behavior is indeed a “male thing,” it should be most likely to occur when males show off and compete directly with each other for status (and ultimately for mating opportunities). In a series of laboratory studies, McAndrew and Perilloux (2012) demonstrated that men were most likely to volunteer for physically costly experiences (experiencing pain and getting soaked in a dunk tank without any advance notice) so that their

group could win money when there was both a female *and* another male present in a three-person group. Their studies also confirmed that those who volunteered for such activities were liked better, were rewarded with more money, and were preferred as future work partners by their colleagues in the experiment.

Conspicuous Consumption as Costly Signaling

Perhaps the most readily observable form of costly signaling in capitalistic societies is wasteful spending on luxury goods that by definition are not essential for survival, or even for comfort, in daily life. This “conspicuous consumption” is driven by a desire for status and the clear signaling of this status to onlookers (Saad 2007). In a series of seven studies, Nelissen and Meijers (2011) confirmed that wearing brand label clothing does indeed increase perceptions of a person’s wealth and status, and that this perception leads to all sorts of advantages. Specifically, these studies demonstrated that individuals wearing expensive branded clothing are more likely to gain compliance to their requests, be recommended for jobs and higher salaries, achieve better outcomes in social dilemma and dictator games, and that they are more successful when soliciting charitable donations from others. Griskevicius et al. (2010) have also determined that people buy expensive, environmentally friendly products specifically to boost perceptions of status and to advertise their own altruistic tendencies.

A number of studies have highlighted how closely conspicuous consumption as a costly signal is tied to mating motives. Wang and Griskevicius (2014) found that the need to guard their mates and ward off mate poachers triggers displays of luxury goods by women who wish to deter rivals by demonstrating the depth of their mates’ devotion. Similarly, Hennighausen et al. (2016) found that priming men with concerns about competition with other men for status leads to an increased interest in acquiring luxury goods such as expensive cars, and that males are

predisposed to see other men who own luxury cars as potential rivals than as potential friends. Saad (2011) has even reported that men's testosterone levels increase after publicly driving an expensive Porsche automobile and decrease when driving a beat-up old Toyota sedan.

However, the mating advantages of conspicuous consumption are apparently limited. Conspicuous consumption by men primarily reflects an interest in short-term mating rather than long-term mating, and this is accurately detected by females who nonetheless judge conspicuous consumers to be more desirable as short-term (but not as long-term) mates (Hennighausen et al. 2016; Sundie et al. 2011).

Many anthropologists have studied how expensive cultural rituals such as wedding receptions translate into costly signals. For example, Bloch et al. (2004) examined how the notoriously over-the-top lavishness of Indian weddings (paid for by the bride's family) came to be. The dowry (bride price) and the wedding reception can cost the family up to six times their annual income, and it is one of the leading causes of debt among Indian families. Bloch and his colleagues interviewed many Indian families about just this issue. The status of Indian families is strongly linked to the importance of the people that they know and the size of their social network, and wedding receptions are an ideal venue for expanding and advertising the nature of this network. Their interviewees emphasized the importance of "making a good show" and they were keenly aware that the details of the wedding would be discussed by others. Marriage in general and the wedding in particular therefore become key ways of signaling prestige. Lavish weddings are especially important signals when the groom's family comes from a different village where the exact social standing of the bride's family may be unknown; they have less social impact when everyone in town already has in-depth knowledge of a family's economic situation. So, Bloch et al. (2004, p. 690) concluded that "wedding celebrations are a form of conspicuous consumption that signals the family's social status to the community."

Religious Commitment as Costly Signaling

Evolutionary psychologists have long thought of religion as a social mechanism for enforcing cooperation within cultural groups (Wilson 2002). One of the ways in which it may successfully accomplish is by using religious commitment as a costly signaling device (Henrich 2009). All religions have rituals, taboos, and other requirements that can be very costly in terms of time, money, or effort. Fasting, tithing, frequent and lengthy prayer and/or religious services, and dietary requirements that are difficult to maintain require a good deal of commitment. Thus, religious commitment can be a hard to fake signal of commitment to the group's values and a signal that one is likely to be a reliable, cooperative group member. Sosis and Bressler (2003) conducted a historical analysis of communal societies and discovered that the ones with the costliest membership requirements survived for the longest times but only if the commune had an underlying religious reason for existence. Soler (2012) found that religious commitment predicted generosity in economic games and self-reported acts of generosity among adherents to an Afro-Brazilian religion in Brazil.

Conclusion

Costly signaling theory provides a compelling rationale for altruistic acts that are not easily explainable by other mechanisms such as kin recognition or reciprocal altruism. Costly signaling occurs in a wide range of social situations such as consumer behavior, philanthropy, heroic action, and religious activity. Such costly signaling helps maintain social groups by providing honest information about the traits, resources, and behavior patterns of individuals who are members of those groups. All available evidence indicates that costly signaling does in fact result in rewards for the altruist in the form of increased mating opportunities, access to resources, and positive attention from others.

Costs and Benefits of a Large Brain

Matthew Chason and Richard Holler
State University of New York,
New Paltz, NY, USA

Synonyms

Brain evolution; Consequences of possessing a large brain; Incurrences of higher cognition; Privileges of the human brain

Definition

Humans are distinct from all other forms of life by the hub of their central nervous system, the brain,

which serves as both the most powerful and most exhausting human asset.

Introduction

It is critical to an organism's fitness to receive and to respond to information from its environments. The ability to process external information has become a driving force of evolution. As a result of various selection pressures over an extensive period of time, the most complex information processing system was engineered, the brain. Increased brain size and neuronal connections granted modern humans or *Homo sapiens* incredible perceptual capacities, such as consciousness and theory of mind. Although positioned as benefits in the context of being able to interact with the environment, there are also costs to operate the complex cognitive processes.

Evolution of the Mammalian Brain

The mammalian brain has a unique trait of changing shape as it matures. The cortical surface areas and volumes are relatively much larger than other species' cortical structures in the animal kingdom. Brains of mammals, especially primates, became more convoluted as it evolved a larger volume. The more the environmental challenges early humans or *hominids* faced became increasingly varied, the more varied their brain morphology became.

About 2.5 million years ago, *homo habilis* lived with an average brain size of 36 cubic in. (Harari 2015). *Homo erectus*, the first recorded humans to be completely bipedal, from almost 2 million years ago, had the privilege to practice hand dexterity. It is hypothesized that the freedom of hands gave rise to environmental manipulation, such as manufacturing tools to facilitate survival.

Today, the average adult *homo sapien* brain ranges from 73 to 85 cubic in. and comprises of billions of neurons (Harari 2015; Hofman 2014); however, it should be noted that *homo*

neanderthalensis or the *Neanderthals* possessed a brain size larger than the brains of *Homo sapiens* (Harari 2015). Although bigger is often better, a bigger brain is far from perfection.

Costs of the Human Brain

The brains of *Homo sapiens* account for 2–3% of their total body mass, yet it consumes about a quarter of the body's energy when at rest. Comparatively, the brains of several primate species consume about 8% of their body's energy when at rest. Given the size of the head relative to its body, combined with the fact that *Homo sapiens* are completely bipedal, its size and weight often are at fault of back aches and neck stiffness. With the increase in brain and skull size also came an increase in infant and mother mortality during childbirth (Harari 2015).

As a result of increased brain size, human offspring are born more underdeveloped compared to many other offspring of primates and mammals. Human babies are extremely fragile and require years of meticulous attention to grow into a healthy child. For instance, a baby's head is so large and heavy relative to its body that unless supported when being held, the baby's neck is at risk of breaking. Moreover, many baby health issues result from the brain's high demand for oxygen. Babies who do not meet this demand often acquire developmental disabilities via brain damage (Harari 2015). Modern human babies require years of being nurtured before becoming completely independent; a human brain takes almost three decades to mature (Arnett 2000).

Healthy brain development requires a substantial amount of energy and resources from the environment. Being deprived of a nutritious diet entails both physical and mental consequences. Infant and child mortality was not uncommon to early humans. Increased brain size within mammalian species is found to correlate with a decreased litter size, which suggests that quality was preferred over quantity (Isler and van Schaik 2009).

The adult human brain is so convoluted that there are a variety of factors that can stir its malfunction. A complex brain with the ability to perceive itself also has the ability to experience pain, negative affective states, and mental disorders (McManus 1997). One in four adults in the United States experiences a mental disorder every year (Duckworth 2013). Mental disorders are notorious for engendering a variety of negative emotions, which can escalate to homicidal and suicidal ideation.

Benefits of the Human Brain

The human brain is capable of possessing a variety of intelligences, some of which are exclusive to humans. Humans are exceptional learners; they are easily capable of solving a variety of problems and can learn from the successes and failures of others. The human brain houses spatial, kinesthetic, mathematical, linguistic, and social intelligences, which enable humans to simulate various scenarios in their environment, determine which foods are safe and unsafe to eat, carve stone, devise animal traps, take care of their young, and treat certain injuries (Harari 2015).

Along with higher intelligence, humans possess theory of mind and consciousness, which provides humans the ability to form mental simulations of others and themselves. Being able to attribute emotional states to others and being able to engage in extrapolation precedes making predictions of other's actions. The traits of precaution, refinement, and better decision-making, among others, are vital for humans to rise to the top of the food chain.

The brain's intelligences would be of little use if it lacked memory systems. Sensory, short-term, and long-term memories store bodies of information from the environment. Organisms that reside in ever-changing environments must find the means to store and retrieve previously processed information in order to adapt. Humans, like most animals, are exploratory creatures; being able to learn from mistakes is the most versatile evolutionary advantage.

Conclusion

The cerebral growth spurt from *homo habilis* to *Homo sapiens* is argued as the most rewarding and most debilitating development of the human. The human brain continues to baffle a wide range of scientists and is likely to remain an enigma for generations to come. It is a privilege to comprehend anything about the complex organ, especially about its impediments. Research in evolutionary psychology is driven by the mysteries of human behavior, which may always remain under the tutelage of the physical brain. Although it may be responsible for countless premature deaths, limited cognitive functioning, and mental illnesses, the brain is also responsible for granting humans the ability to learn, the ultimate adaptation.

Costs and Benefits of Mate Poaching

Ayten Yesim Semchenko¹ and Jan Havlíček^{1,2}

¹Faculty of Science, Charles University,
Prague, Czech Republic

²National Institute of Mental Health, Klecany,
Czech Republic

Synonyms

Human mate poaching; Mate poaching; Sex differences in costs and benefits of mate poaching

Definition

Mate poaching is a behavior intended to lure someone away from their current romantic relationship to form either temporary or permanent relationships with them.

Introduction

Mate poaching appears to be a ubiquitous behavior found in various regions of the world. Schmitt et al. (2004) conducted a survey with 53 nations on 5 continents and found that more than half of men (56.9% for short-term relationships; 57.1% for long-term relationships) tried to poach a mate. The frequency of occurrences was somewhat lower for women (34.9% for short-term relationships; 43.6% for long-term relationships).

For both long- and short-term relationships, around 70% of men and women reported that someone attempted to poach them. The highest rates of mate poaching attempts in a long-term context were reported in the Americas and Europe (56.2–65.6% in men and 43.3–51.5% in women), and a similar pattern was observed in the short-term context (56.7–70.3% in men and 35.5–41.9% in women). In contrast, the lowest rates of mate poaching in the long-term context were found in South/Southeast Asia (38.9% in men and 17.4% in women), while lowest rates in

the short-term context were found in East Asia (29.5% in men and 14.9% in women). Overall, women tried to poach men for long-term relationships more than short-term relationships, while the opposite was true for men. These findings might suggest that mate poaching pays off more for men, in short-term mating.

The potential costs and benefits of mate poaching depend on the perspective of the individual involved. In other words, the perspective of mate poacher, poached one (i.e., the target of the poaching), and poachee (i.e., an individual whose mates were lured away) should be taken into consideration when assessing costs and benefits. For instance, taking pride in conquest is a potential benefit, while having a ready competition with the poachee is a potential cost exclusively for the poacher (Schmitt and Buss 2001). Fearing physical danger from the poachee, however, can be a potential cost for both the poacher and the poached one (Schmitt and Buss 2001; Wilson and Daly 1996). The poachee, on the other hand, might pay the cost of losing a partner.

The costs and benefits associated with mate poaching can be examined on the ultimate and proximate levels. The ultimate level cost-benefit analysis of mate poaching takes both the adaptive challenges that our ancestors may have faced and the adaptive solutions to those problems into account. This level of analysis urges to ask the “why” question to find the evolutionary function of the behavior. The proximate level analysis, however, has to do with the “how” question, and it encompasses immediate assessment of the behavior (Tinbergen 1963; Hladký and Havlíček 2013; Stephen and Sulikowski 2019). In this type of analysis, the flow of events (i.e., response to “how” question) is directly observable, unlike ultimate level analysis. The main aim of this entry is to provide an overview of ultimate and proximate costs and benefits associated with mate poaching. Several factors, such as type of the relationship desired by the poacher, sex differences, gender equality, socioeconomic status, and sex ratio, can potentially affect the costs and benefits of mate poaching. Costs and benefits linked with mate poaching will be explained and exemplified through these factors.

The Relationship Types and Sex Differences

Mate poachers aim to establish either short-term (i.e., temporary) or long-term (i.e., permanent) relationships with the poached. The type of desired relationships affects the potential costs and benefits of mate poaching. For instance, several proximate costs such as guilt feelings, deception issues, dating isolation (i.e., having to hide when on a date), and family rejection were reported as costlier in poaching for a long-term relationship compared to a short-term relationship for both sexes (Schmitt and Buss 2001).

Furthermore, the type of relationship that is being encroached on might also affect the potential costs and benefits of mate poaching. Davies and Shackelford (2017) found that the poached person expected more resources and physical attractiveness (compared to their current partner) when they were married as opposed to cohabitating and when they were cohabitating as opposed to dating. Similarly, Schmitt and Buss (2001) reported that both men and women were perceived as less successful in poaching women/men who have committed relationships as opposed to uncommitted relationships. Therefore, target individuals' current relationship status and investment affected their perception of the trade-off between the cost and benefit of being poached.

Together with the relationship types, sex differences also play a crucial role in the potential costs and benefits associated with mate poaching. An ultimate benefit of mate poaching is an increase in reproductive success. For men, the minimum parental investment required is only the copulation time, while for women, it is at least 9 months of pregnancy (Trivers 1972). Therefore, men can increase their reproductive success by having a higher number of partners. Relatedly, Schmitt and Buss (2001) found that enjoying sexual variety was labeled by the participants as a potential (proximate) benefit of mate poaching for men. In line with that idea, men might see more benefit in poaching for short-term relationships than for long-term relationships as compared to women. Schmitt and Buss (2001) found that the percentage of men (64%)

attempting to poach for a short-term relationship was higher than the percentage of women for the same purpose (49%).

More women (63%) than men reported to attempt poaching for a long-term relationship (52%). However, men, more than women, attempted to poach for both long- and short-term relationships in all regions (Schmitt et al. 2004). In line with this finding and compared to men, women perceived a higher cost of reputational damage and shame if they poach for short- or long-term sexual affairs or a new exclusive relationship (Davies et al. 2010).

Furthermore, Schmitt and Buss (2001) found that for short-term mate poaching, men perceived a greater benefit of taking pride in conquest, while women perceived the same benefit more than men in the long-term mate poaching context. Relatedly, men perceived more benefit of ego-boosting in mate poaching for a short-term relationship when compared to women (Davies et al. 2010). Consistent with their tendency for short-term matings with a lower commitment, men found more benefit in enjoying a lack of responsibility and always having time off from a relationship compared to women (Schmitt and Buss 2001).

Men can increase their reproductive success by having physically attractive partners. Previous studies showed that female physical attractiveness (e.g., waist-to-hip ratio and lumbar curvature) might indicate fertility (Singh 1993; Lewis et al. 2015). Therefore, having a physically attractive partner is a potential proximate benefit for men both as a poacher and poached.

Throughout human evolutionary history, the particular cost of fathering someone else's offspring has exclusively applied to men (Buss and Schmitt 1993). Therefore, to ensure their fatherhood, men might show sexual proprietariness (Buss and Schmitt 1993). One potential consequence of male sexual proprietariness might be murder, including wife killings (Wilson and Daly 1996; Buss 2005). In other words, having a physical danger might be a potential proximate cost for both the male poacher and the poached female.

The cost of fearing physical danger was rated more highly for men than for women by the

participants (Schmitt and Buss 2001). However, Davies et al. (2010) found that women who poached for an exclusive relationship saw a greater cost of being physically harmed by the poached partner. The difference between these two studies might be due to the variation in methods of perspective given (i.e., third-person perspective, Schmitt and Buss 2001; first-person perspective, Davies et al. 2010).

Women can increase their reproductive success by having men who are willing to and have the means to provide for themselves and their offspring. Therefore, gaining resources can be the proximate benefit for females. Schmitt and Buss (2001) found that gaining resources was attributed as a benefit for female poachers. Relatedly, resource depletion might be a proximate cost for men (Schmitt and Buss 2001).

For both sexes, most mate poaching attempts appear to result in success. Schmitt et al. (2004) found that over 65% of men and women reported successfully poaching a mate away as a short-term mate and a long-term mate. More than half of men reported to be either poached away as a short-term or as a long-term partner. Over 40% of women were successfully poached away as a short-term mate, except in South/Southeast Asia (28%) and Africa (26.9%). More than 42% of women were poached away as a long-term partner worldwide. Arnocky et al. (2013) found that the number of mate poaching attempts was a significant predictor of lifetime sex partners, lifetime casual sex partners, and lifetime dating partners. However, another study showed that relationships formed via poaching function rather poorly. There were lower levels of commitment and investment and less satisfaction, and the rates of infidelity were higher compared to the other relationships formed differently (Foster et al. 2014). The quality of the resulting relationships might also be affected by the friendship between the poacher and the poached. For instance, it was found that poachers were seen as less likely to commit infidelity when the poacher and the poached were friends. Furthermore, their relationships were considered more likely to last over a year (Mogilski and Wade 2013). Friendship might signal commitment. Therefore, the likelihood of experiencing

the proximate cost of future infidelity might be reduced.

Having a pre-approved partner can increase reproductive success, especially for women. As mentioned above, women can increase their reproductive success by being with men who can and are willing to provide resources for them and for their offspring (Schmitt and Buss 2001). These characteristics may not be readily available from the visual cues. Therefore, by copying the preferences of other women and poaching a coupled man, women can lower the cost of selecting a mate (e.g., time being spent and choosing a mate low in quality). On the other hand, the female body can signal fertility more readily than the male body (Perilloux and Cloud 2019). Therefore, men can use physical cues to assess women's mate value. Furthermore, preferring women with partner can lead to an unwanted consequence of misdirecting parental investment (Hill and Buss 2008). Therefore, having a pre-approved partner can be a proximate benefit of mate poaching for women rather than men.

The results of studies on female mate copying, however, have shown contradictory results. It was found that women perceive the male targets presented with females as more attractive (Gouda-Vossos et al. 2018) and that mate copying is more common among young women compared to older women (Anderson and Surbey 2014). However, Parker and Burkley (2009) found that only single women showed a preference for the attached men compared to single men. In another study, women did not perceive engaged or in-a-relationship men as more attractive or as having higher socioeconomic status (Uller and Johansson 2003).

A study conducted with male participants tested the mate copying effect. The findings suggest that men perceived the female images with the title "with a partner" as socially more distant compared to the female images with the title "without a partner" (Ueda et al. 2017). The two-thirds of the participants indicated a lower desire to have a romantic relationship with the partnered females in the images. They also show that this effect was accompanied by the parietal cortex activation. The parietal cortex is associated with social distance evaluation, the analysis of the

complex network of social relationships based on physical distance, such as close and distant friends (Yamakawa et al. 2009). The participants preferring females with partners, in contrast, had a higher orbitofrontal cortex activity (Ueda et al. 2017). This region of the brain is linked with risk-taking (Hsu et al. 2005) and with subjective ranking of visual objects (Lebreton et al. 2009).

In line with the studies discussed above, Davies et al. (2010) found that both men and women would be averse to mated individuals when they are equally attracted to single and already-mated ones. These findings collectively suggest that the costs of mate poaching might under many circumstances exceed the benefits for the poacher.

Cultural and Environmental Factors

Gender equality, socioeconomic status, and sex ratio might affect the cost-benefit assessment of mate poaching. For instance, Davies et al. (2010) found that the perceived cost of mate poaching was higher among women than men. This difference might explain why men attempt to poach more than women (Schmitt et al. 2004). In line with that logic, Schmitt et al. (2004) found that in gender-equal regions, sex differences tend to shrink for poaching a short-term partner. This finding mainly stemmed from the women's increased poaching attempts. Furthermore, there was a negative correlation between men's poaching attempts for long-term relationships and gender egalitarianism (i.e., equal access to political and economic power). Women's mate poaching attempts were, on the other hand, positively correlated with gender egalitarianism. Furthermore, both men and women showed increased poaching attempts when women have more political power indexed by the proportion of women in parliament. There was a positive correlation between political equity (i.e., equal access to political power) and women's both short- and long-term poaching attempts and their prevalence. Political equity was also positively associated with the occurrence of men's short-term mate poaching attempts.

Socioeconomic status can also have an impact on the potential costs and benefits of mate poaching. Schmitt et al. (2004) found that men who engage in short-term mate poaching attempts more had a higher socioeconomic status in many regions (i.e., North America, Western Europe, the Middle East, and Africa). Women also showed a similar tendency in certain regions of Southern Europe, South/Southeast Asia, and East Asia. Furthermore, for both sexes, the successful short-term mate poaching attempts were positively related to the socioeconomic status of the participants. Men's failure to resist short-term mate poaching attempts was also positively linked to socioeconomic status. Therefore, for both poacher and the poached, socioeconomic status affects the costs and benefits of mate poaching.

Lastly, sex ratio might also affect the costs and benefits associated with mate poaching. The available mating pool might shrink for the more prevalent sex when the sex ratio is skewed. This reduced availability might motivate mate poaching by potentially increasing the reproductive success of the more prevalent sex. In other words, the benefits of mate poaching might be higher for the more prevalent sex compared to the rarer sex. As expected, the prevalence of female mate poaching attempts was negatively linked to their sex ratio (Schmitt et al. 2004). However, when the male sex ratio was higher, men showed fewer attempts of mate poaching. Furthermore, in the regions where there is a surplus of women, mate poaching rates showed a trend to increase. Therefore, the potential effect of sex ratio on the cost-benefit assessment of mate poaching was only partially supported.

Future Directions

The number of studies on the costs and benefits of mate poaching is somewhat limited. Indirect evidence from uxoricide (i.e., wife killing), infidelity research, and mate copying research have been commonly used in the mate poaching literature. However, uxoricide or extra-pair affairs do not always encompass mate poaching. For instance,

if a married woman pursues a single potential partner and eventually has an affair, it falls into the definition of an extra-pair affair but not of mate poaching. Similarly, mate copying does not necessarily indicate mate poaching behavior. It might merely show the preferences of same-sex individuals. Therefore, future studies are needed in order to have a better understanding of the costs and benefits of mate poaching behavior. Furthermore, to our knowledge, none of the studies directly investigating the cost-benefits associated with mate poaching used the interview method. Qualitative studies with in-depth interviews might shed light on proximate costs and benefits further by exploring variation in contexts of mate poaching behavior.

Conclusions

Mate poaching appears to be a widespread human experience. Almost 70% of people claim that someone attempted to poach them, and nearly half of them reported to fail resisting it. Although it is a ubiquitous experience, the findings suggest that mate poaching may not be the first preference of most people when seeking a mate, possibly due to its potential costs.

There are various potential ultimate and proximate costs and benefits associated with mate poaching. Having a higher reproductive success is a potential ultimate benefit, while taking pride in conquest, gaining resources, and enjoying a sexual variety are among the proximate benefits. The potential ultimate cost of mate poaching is a lowered reproductive success; while future infidelity concerns, ready competition with the poachee, and resource depletion are the examples of the proximate costs.

Several factors affect the cost-benefit assessment of mate poaching for both the poacher and the poached individual. The types of relationships desired by the poacher and the type of target relationship being encroached on, sex differences, cultural and environmental factors (i.e., gender equality, socioeconomic status, and sex ratio) are among those factors. Future studies are needed to have more in-depth information about the context

of mate poaching. Having a detailed picture of the mate poaching context will lead to a better understanding of its costs and benefits.

Aggressive behavior; Violence

Definition

The price individuals pay when they behave aggressively toward others.

Introduction

Although aggression can serve many different functions, or no function at all, the function for which aggression presumably evolved, and which presumably accounts for most occurrences of aggression in modern human life, is competition.

In other words, aggression allows one individual to obtain a resource from another one; improve his/her status over another one; coerce another individual into an activity that is against his/her interests; reduce the competitive ability of another individual in physical, social, or psychological ways; or eliminate a competitor altogether.

By definition, competitive aggression toward another individual inflicts costs, and brings no benefit, to this individual (otherwise it would not be called aggression but punishment or something else). From an evolutionary perspective, the costs of aggression to the target or victim imply a reduction in this individual's probability to survive or reproduce. In everyday life, relatively minor forms of aggression may not necessarily impair another person's survival or reproduction but nevertheless can induce a variety of different costs: physical, social, psychological, reputational costs, or costs in terms of lost time or energy or missed opportunities to engage in other beneficial activities.

The analysis of aggressive behavior from an evolutionary perspective or the perspective of rational theory used by economists leads to similar predictions regarding the occurrence of aggression: aggression should occur only when it brings a competitive advantage to the actor (Georgiev et al. 2013). The competitive advantage to the actor can take two different forms, which correspond to two distinct forms of aggression: selfish and spiteful aggression. Selfish aggression, by the definition, entails costs and benefits to the actor and costs to the recipient. This form of aggression should occur whenever the benefits of aggression to the actor are greater than the costs of aggression to the actor. Spiteful aggression, instead, entails no direct benefits to the actor but costs to the actor and costs to the recipient. This form of aggression should occur whenever the costs of aggression to the recipient are greater than the costs of aggression to the actor.

In order to understand human aggression from an evolutionary or rational perspective, it is crucial to identify, quantify, and fully understand the benefits of aggression to the actor, the costs to the actor, and the costs to the recipient (Georgiev et al. 2013). The benefits of aggression

to the actor depend on what competitive aggression is about, including the value of the resource being contested. The costs of aggression to the victim may depend on many different variables including, among others, the intensity of aggression and the characteristics of the victim. The costs of aggression to the actor are typically independent from what competitive aggression is about or the characteristics of the victim. Instead, the costs of aggression to the actor largely depend on how aggression is delivered.

Whether aggression is selfish or spiteful, it is in the aggressor's best interests to always minimize the costs of aggression to himself/herself. Evolutionary theory predicts that the most costly forms of aggression, which involve the death of aggressor, can only evolve through kin selection (or, at least in theory, group selection) in relatively extreme and unusual circumstances. One of them is self-sacrifice to protect many highly related individuals: a good example is wasps or honeybees that die after they sting an intruder in order to protect the closely related members of their colony. Another rare and unusual circumstance would involve the use of highly devastating forms of spiteful aggression, such as suicide bombing. Individuals who self-sacrifice in this way can help their relatives (or members of their group) by eliminating large numbers of their competitors.

Whenever aggression is maintained by individual selection, rather than kin or group selection, there is selective pressure on the individuals (or incentives, in the framework of economists' rational theory) to keep the costs of aggression as low as possible. The extent to which the costs of aggression can be minimized is a crucial factor influencing the occurrence, frequency, and intensity of aggression. Other things being equal, the low costs of aggression can promote the occurrence of frequent and intense opportunistic aggression, while the high costs of aggression can act as a brake on the individuals' tendency to use aggressive strategies for competition.

A great deal of variation in the costs of aggression occurs both among different species and within the same species. Large differences in the

costs of aggression among species are associated with species differences in body size, weaponry, mobility, and social organization. Aggression is more costly in large mammals with horns, fangs, and claws than in the sedentary and peaceful polyps of the coral reef. Within species, some variation in the costs of aggression can be associated with age, sex, and body size. The costs of aggression are probably higher if it involves heavyweight boxing champions than 3-year-old kids. A great deal of interindividual variation in the costs of aggression within the same species, however, is strategic in nature, as it may depend on individual strategies regarding how and when to deliver aggression.

The rest of this chapter will be focused on interindividual variation in the costs of aggression in humans, with particular emphasis on the strategies people use to deliver aggression toward others, while minimizing the costs to themselves. For the sake of the analysis, a distinction can be made between situations in which aggression only involves two individuals, the aggressor and the victim, and situations in which multiple aggressors and/or multiple victims are involved. Some strategies for reducing the costs of aggression can apply to both types of situations, while some highly complex social strategies apply only to situations involving multiple aggressors or multiple victims. It is also useful to make a distinction between different types of costs of aggression, such as risk of physical injury or death; psychological pain or stress; retaliation against self, relatives, friends, or property; reputational damage; and waste of time and energy.

The Costs of Human Aggression

In direct one-on-one physical combat, one obvious way to reduce the risk of injury is to wear protective gear or armor. Whenever weapons are used, there is always the risk of accidental self-harm (e.g., an aggressor using a knife could accidentally cut himself/herself during combat, or a soldier could accidentally blow himself/herself up

with a grenade). All projectile weapons, however, reduce dramatically the risk that the aggressor may be harmed by the victim, by increasing the distance from the victim. This is true for anything that can be launched (a rock, a spear, a grenade) as well as for all firearms. Guns reduce greatly the costs of aggression relative to knives. One of the most effective ways to attack others at a minimal cost to the self is to launch a missile or drop or detonate a bomb from a great distance from the target by simply pressing a button. Hurting others from a distance can be very quick and effective; not seeing the victim while he or she is being hurt or killed can reduce dramatically the psychological costs of aggression, i.e., the notion that we are, under normal circumstances, naturally inhibited against harming others directly and/or suffer psychologically at the sight of other people being in pain.

While there is always a certain risk that a victim of aggression may hurt the aggressor during combat, there is also the risk that the victim will retaliate later against the aggressor himself, his/her relatives or friends, or even his/her property. One key strategy for the aggressor to reduce the retaliatory costs of aggression is to conceal his/her identity. In direct face-to-face combat, this can be accomplished by wearing a mask. When aggressor and victim are not in direct visual contact, the aggressor can ensure that the source of the attack remains anonymous. Anonymity can have a dramatic effect on the reduction of the costs of aggression and therefore enhance the probability of aggression itself.

The opportunity to deliver anonymous aggression is as advantageous as the opportunity to steal money or goods from others without any prospect of punishment.

Whenever multiple individuals are involved as aggressors, and one or more as victims, it always pays for the aggressors to outnumber the victims. The higher the number of aggressors, the lower the costs of aggression to them, for many reasons. If direct combat is involved, the victim's ability to hurt the aggressors is reduced if multiple aggressors are involved. The time and energy costs of aggression are also reduced with multiple aggressors. The psychological costs of aggression are

reduced because moral responsibility for hurting the victim and empathy for the victim's pain are shared and diluted among multiple aggressors. Finally, if retaliation from the victim, or the victim's relatives/allies occurs, the probability of being the target of retaliation is diluted among all aggressors. If aggressors act as a group, there may be no moral, social, or legal sanctions either, especially if that group itself is responsible for establishing or enforcing the moral, social, or legal norms. When a large crowd of individuals attacks one or more targets (mobbing), there is also further reduction of costs due to the anonymity of individuals within the crowd. For socially complex species, group aggression toward individuals or minority groups is highly significant, is likely to occur whenever favorable circumstances arise, and can have potentially devastating consequences including genocide.

Computer-based communication has provided new opportunities for expressing low-cost aggression, thereby promoting new, frequent, and troubling kinds of aggression. Emails may allow individuals to verbally attack others, including complete strangers, without incurring any significant costs. Sending offensive emails from anonymous accounts also minimizes the risk of later retaliation. Posting anonymous attacks on public Internet outlets, such as Amazon.com, where people can post book reviews as vehicles for personal attacks against the book's authors, also involves minimal costs. Given the current deregulated nature of Internet-based communication, blogs, including anonymous ones, provide a platform from which to launch low-cost attacks against individuals or minority groups. Given that posted material on the Internet is not easily removed and can be quickly and effectively retrieved by search engines such as Google, defamatory attacks are cheap but highly effective ways to inflict high reputational damage to individuals. Finally, social media such as Twitter and Facebook offer the opportunity to engage in mobbing, which has virtually no cost to the aggressors but potentially devastating consequences for the victim. To give an example of this mobbing and its consequences, an American woman named Justine Sacco, who made an inappropriate comment on her

Twitter account in New York while boarding a plane flying to South Africa on December 20, 2013, was the victim of rapid vicious attacks by thousands of Twitter users, some of which were addressed to the woman's employer and demanded her firing (Ronson 2015). When the woman's plane landed in South Africa and she checked her email and Twitter accounts again, she discovered that she had been fired by her employer and had been victimized on Twitter by thousands of strangers around the world. In addition to losing her job, the woman had to deal with the psychological trauma from the experience and the damage to her reputation that might potentially affect the rest of her personal and professional life. None of the Twitter aggressors paid any consequences whatsoever for their actions.

Given its characteristics, Twitter has become an ideal tool for low-cost ad hominem attacks. In fact, a category of professional Twitter aggressors, known as Trolls, has emerged, whose main activity is to insult, offend, and defame individuals who become someone's targets. While victims can limit the damage of this aggression by closing their Twitter accounts and limiting their presence on social media or other Internet outlets, reputational damages can still occur. Wikipedia profiles, which are typically reserved to individuals with positive accomplishments for society, are also frequently targeted by anonymous attacks and must be constantly and carefully patrolled by an army of Wikipedia editors, to prevent these attacks from emerging to the surface. These attempted attacks, however, leave traces on the "history" menu of the Wikipedia pages.

Conclusion

It is well established that human beings have a high potential for aggression but also that the expression of aggression is very sensitive to fluctuations in its costs and benefits. Human population on this planet has been growing exponentially, while natural and other resources remain limited. Increasing competition in human societies unfortunately means that the potential benefits of aggression will increase as well. For

example, we may hypothetically reach a time in future in which drinking water is so scarce and so valuable for survival to tempt people to kill each other over a bottle of water. The increased scarcity and value of resources, however, is not the only factor that can increase aggression. Reduced costs of aggression can produce the same outcome. Some social and cognitive characteristics of the human species and of human societies make it possible for us to express frequent and potentially lethal low-cost aggression. First, we are a highly social species and live in huge societies comprising millions of strangers. Although we are remarkable in our capacity to tolerate and to cooperate with strangers, this also means that we are able to form aggressive coalitions involving many strangers against our competitors. The low costs of group aggression in which aggressors largely outnumber their victims make group aggression, such as mobbing, potentially lethal for individuals and for minority groups who become targets. Second, in addition to our high sociality, our cognitive skills allow us to reduce the costs of aggression by concealing our identity or engaging in other forms of deception that may reduce the probability of retaliation. We also possess the cognitive skills to reduce the psychological costs of aggression, for example, by altering our moral and empathic inhibitions against hurting others. Finally, our technology can further reduce the costs of aggression by allowing us to protect ourselves while attacking others, attack others from a long distance and without visual contact with our victims, and attack others using technology-based communication such as the Internet, in which massive anonymous attacks against individuals can be quickly mounted at virtually no cost to the aggressors.

When Al Gore invented the Internet, he clearly had no idea that Twitter and other social media would lead to the creation of Trolls and the proliferation of online mobbing. New computer technology interacts with ancient aspects of human nature in novel and unexpected ways. The autistic geniuses of Silicon Valley should hire human nature experts such as myself as consultants.

Costs of Punishing

Nikos Nikiforakis
Social Science Division, New York University
Abu Dhabi, Abu Dhabi, United Arab Emirates

Synonyms

[Costs of retaliation](#); [Revenge](#)

Definition

The payoff or fitness reduction resulting from the punishment of norm violators.

Introduction

The willingness to punish selfish behavior is believed to play a key role in promoting cooperation in daily life. This entry provides an overview of what is known about the costs of punishing:

why they matter, what they imply for cooperation, and what they comprise of. The focus here will be on informal punishment, i.e., peer-to-peer punishment, a topic of intense investigation in the past decade. The case of formal or institutional punishment is not considered here. As it turns out, we know a fair amount about why the costs of punishment matter and what they imply for cooperation, but relatively little about what they comprise of.

Costs of Punishing

At the most fundamental level, the costs of punishing can be divided into two categories: those incurred by punishers and those incurred by the targets. Theoretical models and laboratory experiments clearly illustrate that both matter a great deal. From an evolutionary perspective, the costs incurred by punishers imply that punishers have a disadvantage in terms of fitness relative to non-punishers. Consequently, as these costs increase, the more difficult it is for the propensity to punish to evolve and be sustained in the long run (e.g., Dreber et al. 2008). In line with this, laboratory studies have shown that individuals are less willing to punish selfish (or antisocial) behavior as the monetary cost of punishment increases. On the other hand, the costs incurred by potential targets of punishment have the opposite effect, making selfish behavior less attractive. Laboratory evidence shows that as the monetary cost for targets increases, so does the level of cooperation. Taken together, this evidence suggests that the prospects for cooperation improve as the punishers' costs fall and that of the targets increase, that the costs incurred by punishers have to be substantially lower than that incurred by the targets for the threat of punishment to lead to high levels of cooperation (Egas and Riedl 2008; Nikiforakis and Normann 2008), and that punishers have a tendency to use the least costly forms of punishment (e.g., Balafoutas et al. 2014).

A natural question to ask is what these costs comprise of in daily life. In theoretical models and laboratory experiments, the costs of punishing take the form of a reduction in individual payoffs,

but what may be the cause behind these reductions in reality? To my knowledge, there has been no systematic attempt to answer this key question. Costs can be internal (e.g., guilt, shame) or external (e.g., retaliation, damaged reputation, severed relationships) and depend partly on the form of punishment: direct (i.e., confronting the target) or indirect (i.e., withholding a certain reward from the target). Arguably the main cost for punishers confronting directly their targets is the risk of counter-punishment, as documented both in the lab (e.g., Denant-Boemont et al. 2007; Nikiforakis 2008) and in the field (Balafoutas et al. 2014; Balafoutas et al. 2016). Perhaps surprisingly, punishing a selfish individual to promote cooperation may not improve one's reputation (Balafoutas et al. 2014; Rockenbach and Milinski 2011). On the other hand, punishment targets may suffer from a loss in reputation (Rockenbach and Milinski 2011), feelings of guilt or shame (Hopfensitz and Reuben 2009), and reduced self-image. The costs associated with indirect punishment have been so far less studied, but they are likely to be less substantial, at least for punishers who are unlikely to face counter-punishment (Balafoutas et al. *in press*). Of course this does not rule out that indirect reprisals may be used when indirect punishment is detected. In the long run, these can be quite costly (e.g., severed relations).

Conclusion

The importance of the costs of punishing is well established: the higher the cost for the target and the lower the cost for the punisher, the better the prospects of cooperation will be. There is however clearly a need for studies exploring systematically what the costs of punishing in daily life consist of and their relative importance. The literature suggests that the costs will differ considerably across situations (e.g., Balafoutas et al. 2014), cultures (e.g., Herrmann et al. 2008), and people (e.g., Hopfensitz and Reuben 2009). In any event, a careful analysis of the costs of punishing (alongside the potential benefits of punishment) will reveal when cooperation will be more likely to be achieved by peer-to-peer punishment and

when a different mechanism may be better in deterring free riding.

Costs of Short-Term Mating for Women

Monica A. Koehn and Peter K. Jonason
School of Social Sciences and Psychology,
Western Sydney University, Penrith, NSW,
Australia

Synonyms

[Casual sex](#); [One-night stand](#); [Booty-calls](#); [Hook-ups](#); [Friends with benefits](#)

Definition

The term “short-term mating” typically describes a sexual relationship that is casual in nature, mostly focused on sexual pleasure, lacking commitment or longevity, and characterized by little emotional connection (Jonason 2013; Jonason and Balzarini 2016). The term “casual sex” is used as a catchall to refer to all kinds of short-term relationships, but these relationships can encompass one-night stands, booty-call relationships, hook-ups, and friends with benefits. While all of these relationships have their unique features, they share a common theme of creating a context where individuals have sex without any formal commitment.

Introduction

Casual sex is widespread in nature, with 38% of “adults” (Twenge et al. 2015) and 75% of college students (Jonason and Balzarini 2016) engaging in some form of casual sex relationship. Historically, casual sex has been viewed as a pathology, but this might not necessarily be the case if one takes an evolutionary perspective. Casual sex may be part of the naturally occurring variation in human sexuality.

Ancestrally and today, women (and female mammals) have a heavier obligation to offspring

than men (and male mammals) do, creating different costs and benefits for engaging in casual sex relationships in the sexes (Trivers 1972). This asymmetry has acted as a selection pressure shaping men and women's sexual psychologies differently and translates into men's greater willingness to have sex with a stranger (Clark and Hatfield 1989), to consume pornography, to pay for sex, to have lower standards in who they have sex with, to say "I love you" sooner, and to have more permissive attitudes about sex, findings that hold up cross-culturally (Buss and Schmitt 1993; Schmitt 2005) and over time (Petersen and Hyde 2010). Evolutionary-informed researchers point to the costs and benefits associated with casual sex for men and women as a way to better understand why people may engage in and avoid casual sex along with other relationships (Jonason 2013; Jonason and Balzarini 2016). Various benefits arise out of a short-term mating strategy such as gifts, protection, assessment of own mate value, assessment of a potential partner's characteristics, assessment of sexual compatibility, or gaining superior genetic benefits from a casual sex partner (Buss 2016). Despite these benefits, there are costs and risks to women for engaging in such a strategy. In the rest of this entry, we detail some of the costs women incur by engaging in short-term mating relationships. This is not to say that they do not experience benefits, but that is beyond our scope here.

Social Costs of Casual Sex

Men may be evaluated more favorably, and women are evaluated less favorably for engaging in similar sexual behaviors, an effect called the sexual double standard (Marks 2009). Typically, this double standard is framed in terms of social norms, but such a model fails to consider why those social norms exist in the first place and why women as opposed to men are saddled with the negative reputation for doing the same thing men do. Men's unfavorable evaluations may be driven by men's greater parental uncertainty, that is, their confidence that they are investing in a

biological child. Men who cared more about paternity certainty fathered more offspring than those who cared less. Men are reluctant to enter a relationship with a woman when her previous relationship has ended (Busche et al. 2013) which is claimed to ensure that he will not father a biological child from her previous relationship. Men will judge women with a high number of sexual partners as less desirable for a long-term relationship (Buss 2016) as this is thought to be a signal of future fidelity. These reputational costs may translate into men being less willing to invest in offspring and in her which, overtime, acts as selection pressure against female promiscuity in so much as resulting offspring survive and reproduce less often.

Women risk reputational costs for engaging in short-term mating behavior from women as well. Women engage in intrasexual competition and compete with other women to acquire and retain mates, for social status, and for resources to support their children (Benenson 2013). Furthermore, women engaging in short-term mating lowers the ratio of eligible men available to date (Baumeister et al. 2017). For these reasons, women view promiscuous women as threats to both dating and their relationships. Women disapprovingly evaluate other women with larger numbers of sex partners (Zaikman and Marks 2014). Even while being sexually active and viewing short-term mating as empowering, some women fear their sexual reputation and still believe casual sex is unacceptable for themselves. They will judge other women who engage in casual sex unfavorably even while engaging in the same behavior themselves (Farvid et al. 2017). As well as risking their reputational damage with other women, they forgo friendship opportunities with other women because women dislike sexually permissive women and are less inclined to be friends with sexually permissive women (Vrangalova et al. 2014). Even in cultures where short-term mating is normatively common and socially acceptable, such as Sweden, women who have a reputation for promiscuity will reputationally suffer (Buss 2016).

Health and Reproductive Costs of Casual Sex

If the only costs associated with casual sex in women were social in nature, reducing those costs would be a mere function of changing social norms around sex. However, there are also health and reproductive costs associated with casual sex that women predominantly face. These include sexual violence, sexually transmitted infections, and, also, the possibility of unplanned children. Dating partners may resort to tactics such as coercion, threats, and aggression, progressing ultimately through to rape if a woman does not agree to sexual activity. Women are at a greater risk of physical and sexual assault, with college students experiencing rates up to 27% of date rape, sexual assault, and sexual aggression over their lifetime (Rickert and Wiemann 1998). Sexual assault often results in psychological damage such as trauma, anxiety, depression, fear, guilt, and shame, which are mental health costs. Sexual assault has a reproductive success cost as it threatens women's reproductive choice. Sexual assault resulting in pregnancy dictates the choice of a father, resulting in a child that is fathered by a man whom she potentially would not have chosen and, therefore, may have inferior genes and traits than that she seeks in a partner. This man is unlikely to provide the greatest investment to her and her child. Furthermore, it may prevent a woman from finding a long-term partner willing to take on the parental role for another man's child (Buss 2016).

Methods of birth control such as condoms are required to prevent sexually transmitted infections and diseases. Contraceptives such as the birth control pill only prevent unplanned pregnancies. While contraceptives have allowed humans to separate the acts of sexual activity and reproduction, human psychological mechanisms lag our modern world and have not evolved fast enough to change our mating psychology (Buss 2016). Condom use in casual sex is low with only 47% of students (Lewis et al. 2012) and up to 55% of adults (Sanders et al. 2010) reporting use of a condom during the last casual sex act. This indicates sexual risk-taking, which may further be

exacerbated by the influence of alcohol (Lewis et al. 2012; Owen et al. 2011). Sexually transmitted infections and diseases can in turn affect women's future fertility (Bowden et al. 2002). Reduced fertility affects reproductive success, meaning that women will have lower rates of children or, at the extreme, remain childless and may ultimately threaten long-term relationships (Buss 2016).

Perhaps the largest reproductive cost that women face is unintended pregnancy. In ancestral and modern societies, women face the possibility (more than men) of having an offspring with no support of a father which will face increased childhood mortality risk and potentially maternal mortality as well (Buss 2016). If a modern woman finds herself pregnant from a casual sex encounter, she is stuck between a rock and hard place. She can have an unwanted/unplanned child and rear it as a single mother, remain in a potentially problematic relationship, or have an abortion. These come with costs that women suffer and have suffered asymmetrically more than men did. For example, women undergoing abortions have increased psychological distress such as depression, anxiety, self-judgment, guilt, and shame; experience social judgment from family, friends, and sexual partners; and are often less desirable as dating and long-term partners (Hanschmidt et al. 2016).

Alternatively, a woman may choose to keep the child and raise the child on her own. This will create hardship and stress for both her and her child as single parenting is challenging. Single parents experience financial strain, often resulting in physical illness and mental health difficulties (Stack and Meredith 2018). It is difficult for a woman to find a new long-term partner to invest in her and children from a previous relationship. Some men may not wish to invest their time and financial resources in another man's child. Both partners may face conflicts of interest over providing love and resources to each other or the stepchild. Stepparents are less emotionally invested and devote less time and resources than genetic parents. Furthermore, because the child represents a Darwinian cost to the stepparent, the risk of child abuse by

stepparents is 40 times higher than biological parents (Buss and Duntley 2013).

Mental Health Costs of Casual Sex

Casual sex can be a double-edged sword. Despite women's willingness to enter a short-term relationship (Schmitt 2005), some women experience postcoital psychological distress. Sex for extrinsic motives such as peer pressure, need for self-affirmation, or low self-esteem has been linked to psychological factors such as greater depression, anxiety, and lower self-esteem (Vrangalova 2015). One of the benefits of casual sex is the enjoyment, which is greater for men than women; however, women face greater risks in terms of mental health. For students with no prior depressive symptoms, casual sex has been associated with depressive symptoms over a long-term period (Owen et al. 2011).

Psychological effects can manifest in subclinical areas, for example, postcoital worries and self-esteem issues. Women regret engaging in short-term mating more than men and tend to worry more about factors such as having uncommitted sex, sex with a stranger, one-night stands, progressing relationships too fast sexually, losing virginity too early, or losing their virginity to the wrong person (Galperin et al. 2013). Adult and college student women report feeling used, rejected, embarrassed, reputational loss, self-disappointment, a loss of self-respect, and disappointment that the relationship did not progress to a long-term relationship (Campbell 2008; Lewis et al. 2012). Women who engage in casual sex experience more postcoital worry than men regarding their partner's intentions, being used for sex, and unwanted emotional attachments and experience vulnerability because they may form attachment bonds and are worried about future investment from their partner (Townsend and Wasserman 2011; Townsend et al. 2015).

Indeed, some women may only engage in some forms of casual sex to gain access to higher-quality partners (i.e., hypergamy by casual sex) for long-term relationships (Jonason and Balzarini 2016). That is, they leverage their sexual

availability as a lure to entice a man into a more serious relationship. This is a risky strategy in that couples who know each other better are less likely to use condoms (Sanders et al. 2010), thereby increasing STI and pregnancy risk, but may also translate into depression and postcoital regrets that can affect mental health. Given the postcoital effects of worry, loss of self-esteem, and feelings of rejection, this may have longer-lasting reproductive implications than typically considered. Women may experience a loss in self-perceived mate value and may, therefore, lower the quality of mates they are willing to date, mates who are likely to be less willing/able to invest and may provide lower genetic material to her offspring.

People with psychological conditions such as borderline personality disorder (BPD) are more prone to participate in casual sex, and women are dispositionally more likely to have BPD. Those with BPD are high on impulsivity, including sexual impulsivity. Individuals with BPD have higher rates of unplanned pregnancies and STIs, participate in unprotected sex, have a larger number of casual sex partners, and are more likely to have experienced rape and sexual assault (Frias et al. 2016). Women with BPD who participate in short-term mating may, therefore, be undermining their mental health.

Conclusion

A key insight from evolutionary models of sexuality is that there are reproductive asymmetries in men and women. Men tend to benefit more and pay fewer costs for engaging in short-term mating than women do. Women, in contrast, ancestrally and today, incur more costs for engaging in short-term mating, as summarized in Table 1. We have delineated some of these costs in relation to STIs, single parenthood, child-rearing constraints, mental health effects, and reputational issues. These costs are likely to have shaped women's sexual psychology toward long-term relationships where these costs are minimized. Nevertheless, the mating landscape is still fraught with these dangers, and not all women are disposed to engage in

Costs of Short-Term Mating for Women, Table 1 A summary of the costs of short-term mating in women

Social	Health and reproductive	Mental health
Men may be unlikely to view as desirable for a long-term partner	Physical and sexual assault	Depression, anxiety, lower self-esteem, increased worries
Single parents may face dating challenges	STIs	Vulnerability
Reputational damage from other women	Possible infertility from STIs	Self-respect
Loss of female friends and support network	Unplanned pregnancy	Shame and embarrassment
Less desirable as a future dating partner if having prior terminations	Single parenthood	Trauma from sexual assault
Social judgment from friends and family regarding terminations	Physical illness from financial strain of single parenthood	Anxiety, stress, and depression from financial strain of single parenthood
	Stepparents caring for child	Distress from possible terminations

serious relationships. For those women choosing to engage in short-term mating, they are likely to face these costs in their pursuit of other short-term mating motivations like sexual gratification, testing the waters, and calibrating mate value.

Counter Strategies Against Infanticide

► Infanticide in Nonhumans

Counteradaptations/Female Counterstrategies

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Synonyms

Intersexual competition

Definition

The female response to male attempts to control fertilizations through genital morphology.

Introduction

As stated in “genital evolution,” penises have been selected to confer reproductive benefits for males partially in response to intrasexual selection (competition between males for fertilization) and partially in response to intersexual selection (the

competition between males and females for control over fertilization).

Reproductive Strategies

Humans possess internal fertilization. This is a major factor in human reproduction, as males cannot be sure that fertilization (and therefore paternity) has taken place. This gives females a distinct advantage in confusing paternity, and in some species, expulsing the ejaculate of unwanted partners after coitus (Baker and Bellis 1995). Because of this (and male competition), male genitalia has evolved to overcome these obstacles and increase the probability of fertilization. For example, human penises are longer than other great apes and have a pronounced coronal ridge that assists in semen displacement (see ► [“Genital Evolution”](#)). This penile evolution is actually in response to female genitalia; the vaginas of females of a given species contain long twisted oviducts, enforced walls, acidic mucus, and other facets that help females control fertilizations. As female genitalia shifted to optimize female control over fertilizations, male genitalia evolved to match.

One of the most extreme examples of female genital evolution is in the Lake Duck. The male possesses the longest penis in vertebrates in relation to its body length. This long corkscrew shaped penis matches the female’s long corkscrew vagina. In addition, the female’s vagina contains dead-end sacs, where ejaculate deposition would result in the sperm never reaching its intended destination, and may make female ejection of the ejaculate much easier. This elaborate vaginal morphology appears to have coevolved with male phallus length, which in turn covaries with levels of forced extra-pair copulation. Females attempt to control fertilizations with elaborate genital morphology and behaviors such as ejaculate ejection, while males use elaborate genital morphology and behaviors such as coercion (Brennan et al. 2007).

In humans, females control fertilizations through various behavioral and physiological means. The most influential of these is concealed ovulation (see ► [“Reproductive Suppression and](#)

[Sexual Conflict During Mating”](#)). Due to concealed ovulation, males cannot determine when females are most fertile and must spend more time and invest in females to ensure paternity.

The female reproductive tract is also acidic. The acidity of the vaginal fluid and cervical mucous decreases the longevity of spermatozoa, making it more likely that if any sperm survive long enough to reach the egg, it will be younger, higher quality sperm. This increases the quality of the genes at fertilization. Females also shift risk-taking behaviors with their menstrual cycle (Chavanne and Gallup 1998), taking less risk when they are more fertile. Baker and Bellis (1993) also argue that when females orgasm the cervix uptakes and retains more ejaculate, increasing the probability of conceiving the offspring of males that make them orgasm. Thornhill et al. (1995) argue that these males are more likely to be more symmetrical and have higher quality genes. Baker and Bellis (1993) also argue that females can control fertilization through intercopulatory orgasms. Noncoital orgasms before and after coitus actually increase the acidity of the female reproductive tract, making it more difficult for sperm to survive; this includes both previously deposited sperm that have made it to the cervical crypts and sperm that are yet to be deposited at the next sexual encounter.

Conclusion

In summary, intersexual competition is played out both behaviorally and physiologically, and several strategies are displayed in the biological processes of the genitalia of men and women.

Countershading

Hannah M. Rowland
University of Cambridge, Cambridge, UK
Institute of Zoology, Zoological Society of
London, London, UK

Synonyms

Dorsal pigmentary darkening; Obliterative shading; Optical flattening; Thayer's law

Definition

A form of protective coloration in which the body surface closest to the ambient light source is more darkly pigmented than the body surface furthest from the light source

Introduction

Countershading is a common pattern of coloration in terrestrial and aquatic animals (Rowland 2009). Among marine animals, countershading has been described in the common cuttlefish (*Sepia officinalis*), whale sharks, and the common octopus (*Octopus vulgaris*) and, among terrestrial animals, in moth and butterfly caterpillars, snakes, lizards, birds, amphibians, and mammals including gray squirrels (*Sciurus carolinensis*), naked mole rats (*Heterocephalus glaber*), and many primates.

Countershading is correlated with certain ecological traits (Allen et al. 2012). Small primates that spend more time in horizontal postural positions are more strongly countershaded (Kamilar 2009). Countershaded ruminants have stronger pigment gradients when they live in open lighting environments, live closer to the equator, and are smaller. A distinct demarcation between the dark dorsal side and the light ventral area is also more common in open lighting environments (Allen et al. 2012).

English naturalist Edward Bagner Poulton (1890) and American artist Abbot Thayer (1896) independently proposed that the function of countershading is to conceal. However, there are also other candidate explanations including thermoregulation, protection from ultraviolet radiation, and defense against abrasion.

Improving Background Matching

An animal may more closely match its background if countershaded, especially if it is viewed from different angles (Wallace 1889). For example, when viewed from above against a dark background or from below against a light background (e.g., the sky), a countershaded pattern of dark dorsum and a light ventrum conforms to the general principles of background matching. This could explain the patterning in pelagic fish and seabirds.

Counterbalancing Self-shadows and Disguising 3D Form

Countershading is also hypothesized to counterbalance self-shadowing and obliterate shape-from-shading cues, rendering a prey animal perceptually flat to a viewer. Because sunlight normally comes from above, a uniformly colored animal tends to appear lighter on its upper surface and to have a shadow on its underside. This pattern of differential illumination may diminish an animal's camouflage because it reduces the level of background matching and provides cues to three-dimensional (3D) shape. An inverse pattern of pigmentation to the natural shadows – a dark color closest to sunlight and light pigment on the surface furthest from the light – should cancel out the shadowing and result in a more uniform radiance distribution across the body and improve background matching and diminish 3D cues (Allen et al. 2012; Thayer 1896). Any visual system that relies on shape from shading can be fooled by countershading (Allen et al. 2012).

Evidence for the Camouflage Function of Countershading

The most convincing examples of countershading for camouflage are found in aquatic environments (reviewed by Rowland 2009). In terrestrial systems, countershading is common in lepidopteran caterpillars. Tinbergen (1958) argued that shadowing and the cylindrical shape of larvae would cause them to stand out on otherwise flat leaves, even if their color (before shadowing) matches the background. Rowland et al. (2008) tested the survival of countershading in caterpillars by recording attacks on artificial larvae placed on tree branches in a woodland with variable lighting conditions. The countershaded prey was attacked significantly less frequently than prey with control color patterns.

Other Explanations for Countershading

There are several non-camouflage explanations for countershading. The simplest is that countershading is an epiphenomenon resulting from selection acting on only one body surface because pigments are costly to produce (Ruxton et al. 2004). Functional non-camouflage hypotheses include protection from the damaging effects of ultraviolet (UV) light, thermoregulation, and abrasion protection (reviewed by Rowland 2009). Computational modeling has shown that for animals that can assume any orientation in space, countershading can assist crypsis and favor thermoregulation and UV protection (Penacchio et al. 2015).

Conclusion

There is still much to be tested about the evolution of crypsis through countershading. The effects of direct versus indirect sunlight, orientation, time of day, year, latitude, and background reflectance, as well as orientation behaviors of the countershaded animal, would uncover if countershading enhances crypsis. Furthermore, testing whether nonhuman animals perceive shape from shading cues is necessary. Such tests would show if the predicted predators of countershaded animals derive depth information from shading and if their visual system is fooled by countershading.

Credibility Displays

Adam Tratner

Oakland University, Rochester, MI, USA

Synonyms

Costly displays; Credibility enhancing displays

Definition

A costly display or behavior that provides other individuals with a reliable measure of a person's beliefs or degree of commitment to a group: an ideology, set of values, or beliefs. Ancestral humans faced the adaptive challenge of verifying culturally transmitted information from other people in order to avoid being exploited or misled. Therefore, individuals evolved the ability to attend to credibility displays because they are indicative of one's honest commitment to a group, or a group's beliefs and ideology. Credibility displays promote group cohesion and solidarity because they represent commitment to beliefs that may be collectively beneficial.

Introduction

Researchers have proposed a connection between credibility displays and levels of commitment to group ideologies, religious beliefs, and shared values that promote solidarity and cooperation within groups (Atran and Henrich 2010; Atran and Norenzayan 2004; Henrich 2009). Credibility displays are usually costly, and these costly displays can manifest as a wide variety of behaviors, ranging from charitable acts and extravagant adornment to ritual scarification, animal sacrifice, and self-mutilation. Although such behaviors are seemingly expensive, harmful, and otherwise detrimental to the individual, engaging in costly displays confers an overall benefit by signaling to others one's honest commitment to a belief system, reinforcing one's "credibility" within a

group, and promoting group cohesion between individuals. Natural selection shaped our cognitive processes in regard to cultural learning, such that certain kinds of displays or actions represent important cues of commitment, prestige, and group involvement (Henrich 2009).

The Evolution of Credibility Enhancing Displays

As humans acquired the ability to communicate and engage in cultural transmission using symbolic representations (e.g., language), individuals (i.e., cultural learners) became potentially exploitable by manipulators (i.e., cultural models), who could convey one symbolic, mental representation (i.e., belief), but actually believe something different. That is, manipulators could misrepresent their degree of commitment to a particular belief, provide misleading information, and exploit other individuals who are highly committed. As a result, cultural learners faced this adaptive challenge created by our capacity for symbolic cultural transmission. To address this adaptive challenge, cultural learners evolved the ability to attend to *credibility enhancing displays* (CREDs) – costly displays that provide the cultural learner with a reliable measure of the cultural model's actual degree of commitment to the beliefs that he or she has expressed (e.g., symbolically, verbally; Henrich 2009). The more costly the displays are, the deeper the degree of commitment. If cultural models were willing to incur great costs on behalf of a mental representation (i.e., belief), it would be unlikely that they would believe something different from what they expressed. Therefore, learners could use such displays to determine if they should commit to a particular mental representation, whether it is an ideology, a set of values, or a particular belief.

Credibility Enhancing Displays and Cultural Group Selection

Natural selection circumvented the emergent problem of manipulators by creating a

“cultural immune system” designed to assess a cultural model’s degree of commitment to a belief, judging by their displays (Henrich 2009). Cultural learners could look for displays that are most consistent with the expressed beliefs, as well as identify behaviors and actions that would not be performed by a cultural model who believed something different from what they expressed symbolically. This would in turn create a learning bias, where cultural learners are more likely to acquire culturally transmitted representations (e.g., practices, beliefs, values, strategies) if their cultural models perform costly acts that are both consistent with the underlying representation and inconsistent with alternative representations (Henrich 2009). Further, this learning bias is strengthened when certain CREDs facilitate the transfer of certain beliefs, when a belief favors specific CREDs, and when learners copy the CREDs of successful (e.g., prestigious) individuals. Reliance on CREDs can create stable cultural states, resulting in an interconnected combination of beliefs and practices (Henrich 2009).

Adaptive learning biases lead to the emergence of stable combinations of beliefs and corresponding costly displays. An interconnected system of beliefs could sustain costly practices that facilitate the commitment of other group members and the adoption of beliefs that promote group benefits, such as large-scale cooperation and group solidarity. Thus, CREDs promote success in competition between other social groups because social groups that are comprised of stable combinations of beliefs and practices (e.g., rituals) that favor in-group cooperation, as well as out-group competition, will be able to effectively out-compete other groups (Henrich 2009). The presence of multiple groups with stable combinations of beliefs and practices provides the conditions for *cultural group selection*. Social groups that have stable combinations of beliefs and practices that deliver group benefits (e.g., cooperation, solidarity) can spread at the expense of social groups who are less stable or cohesive. Taken together, costly actions and

rituals that facilitate larger-scale cooperation, solidarity, and success in intergroup competition may be a product of evolved cognitive adaptations suited for avoiding exploitation during social learning, in tandem with the process of cultural evolution.

Conclusion

Humans evolved to look for *credibility enhancing displays* that indicate a cultural model’s degree of commitment to, or belief in, expressed mental representations. Credibility displays are actions that are both consistent with a model’s professed beliefs and that would be unlikely to perform if he or she believed something different from what he or she expressed. Natural selection favored a reliance on CREDs in determining how much to commit to, or believe in, a particular representation. Participation in costly displays is associated with prosocial in-group behavior, because costly displays indicate commitment to beliefs that may benefit the group as a whole. Groups that require costly displays are favored by cultural evolution because costly displays are honest signals of belief commitment and thereby promote cooperation and success in inter-group competition (see Henrich 2009). *Cultural group selection*, then, spreads interconnected combinations of beliefs and practices, where stable combinations of beliefs and practices promote a group’s success over others.

The existence of credibility displays was presumably initiated by an evolved learning bias, which preferred costly displays because they signified greater commitment to a group, or a group’s beliefs and ideology. The more costly the displays are, the deeper the degree of commitment. The evolved psychological processes underlying the strong preference for credibility displays may illuminate a number of peculiar, costly aspects of group commitment. For example, religions often value individuals who make costly sacrifices, such as martyrdom, self-imposed poverty, celibacy, and sobriety (Atran and Norenzayan 2004).

Criminal Personality Variables

Roger S. Sousa¹ and Sophia Lóren de Holanda Sousa²

¹Universidade Federal do Ceará, Fortaleza, CE, Brazil

²Department of Psychology, Universidade Federal do Ceará, Fortaleza, Brazil

Synonyms

[Criminal personality](#); [Individual aspects related to criminal behavior](#)

Definition

Criminal personality variables are understood as individual aspects that seem to influence involvement in criminal behavior.

Introduction

Criminal behavior is related to several variables, both environmental and individual. Several researchers point out different elements for the explanation of crime starting from the various theoretical points of view. Criminology has added most of these explanations to a field of study and practice as it constitutes an overlap of several sciences. Among these, psychology has made several contributions, both in theorizing and in intervening in criminal behavior. One of the main elements of study within psychology, more specifically investigations of criminal behavior, is personality.

In the field of psychology, personality is one of the most frequently studied and debated concepts. However, Allport (1955) already argued that personality is a very complex concept to be summed up. In general, for him, facets of personality guide specific behaviors and ideas, representing a more stable tendency to act, feel, and think. Variables of personality have long been used to explain criminal behavior. However, evolutionary psychology has not always assisted in the development of research in this area. However, personality has also been studied from the standpoint of evolutionary psychology, which has developed theories about this (life history theory, environmental heterogeneity in fitness optimal and frequency dependent selection), which is better explained throughout this chapter.

In this topic, the term crime is used as shorthand to refer to behaviors that violate laws and social norms. This choice is due to the complexity of the phenomena discussed here, crime and personality, as among these several forms of relationship are observed, depending on the variables of personality and the type of crime chosen. Throughout the topic we try to avoid too much explanation of specific crimes; the intention here

is to introduce the reader to this subject, which may lead them to study in more depth the crime or personality variables that are of interest.

Individual Differences

A major field in psychology, in a general way, is that which researches the differences that any person shows. In many approaches this interest has been present too, and evolutionary psychology is no different. For a long time, the main concern, and consequently the advances, of scientists was to understand, starting from evolution, what might explain many human behaviors. Areas such as sexuality and sexual conflicts, mating strategies, parenting, among many others, have gone through great advances, theoretically and empirically. However, the difference among individuals, and in this context, the personality, had been inadequately explored. More recently, this situation has changed owing to several researchers who have been dedicated to investigating the individual differences (Buss 2009; Del Giudice et al. 2015; Figueredo et al. 2015).

Buss (2009) has already emphasized the importance of investigating individual differences, and he lists four reasons for this. In the first of them he argues that the individual differences have been largely recorded, whether they relate to physical (body type, sleep rhythm, etc.) or psychological (dominance, pleasantness, intelligence, etc.) aspects. In the second reason he claims that most of these differences have hereditary components, besides presenting stability over time. For the third reason he declares that this stability has been revealed as an influencing element in central evolutionary issues, such as survival, mating success, production of offspring, etc. Last, Buss argues that individuals present significant differences between sexes in a feature that already shows differences between sexes. Mating strategies are an example of this. Some individuals may prefer long-term strategies, whereas others would prefer a short-term strategy, and yet others can prefer a mixed mating strategy.

Some of these explanations are presented in a summarized way, to facilitate the understanding of the relationship between personality and crime. The

purpose of this topic is not to discuss the different arguments related to individual differences; we refer the reader to the topic “Evolutionary Personality Psychology” of this encyclopedia, Buss (2009) or Figueredo et al. (2015).

One of the main explanatory theories of individual differences is life history theory. According to this theory, we possess limited resources during life, such as time, energy, the ability to strive, obliging us to trade off among life functions, and consequently resulting in various adaptive problems (Figueredo et al. 2015). Thus, relative to reproductive success, choosing to allocate energy to body development is to abandon developing parenting characteristics, or other types of kind investment, as resources are limited and allocating both requires more than can be offered.

The allocation of accessible resources happens according to several variables, such as qualities and defects of the individual, the life expectancy, the amount of energy available. In dealing with questions related to gene transmission, species that have a large life span end up allocating resources in the development of characteristics related to parenting, as is the case with mammals. However, species with a short life span seem to opt for effective strategies in the short term, experience high fertility with a large number of partners, to the detriment of characteristics associated with parenting, as is the case for most insects (Del Giudice et al. 2015).

In a first look, the life history theory can hold in a clear way the differences between species, as the individual intraspecies differences define an individual's life history orientation. The same way as the distinct environments produced differences among the species, they made differences within the species. If a non-human organism grows in a severe, unpredictable, environment, with a short life span, it is probable that this organism will engage in behaviors that can carry certain risks; furthermore, it will act impulsively and aggressively (Mishra et al. 2017). In the same way, a person who grows up in a social context marked by a short life expectancy can engage in risk behaviors, aimed at satisfying the needs of the moment, giving

scope for engagement in criminal behavior (Richardson et al. 2017).

From this point of view, the social context of the individual has an influence on the resources that the person possesses to invest in certain activities and characteristics of the personality. Thus, being poor, single, with low educational achievement increase the chances of engaging in strategies that present more immediate results, which are sometimes impulsive and involve risks. This context can provoke a short life span, considering that one consequence of this is the use of the previously described strategies. The context in which the individual is inserted is also considered to be fundamental for the explanation of individual differences by another approach, the environmental heterogeneity in fitness optima.

According to the idea of the environmental heterogeneity in fitness optima, the environment where the individual lives can favor different levels of certain feature. Some places would endorse particular characteristics of the personality as this level of a characteristic can guarantee more resources, as in the case of a risk-taking personality. By this logic, individuals raised in large cities end up developing personality traits distinct from those residing in small towns, to ensure maximum access to possible resources, in addition to survival.

Several other approaches are made to elucidate the mechanisms that support differences between individuals. Some start from the notion of genetic mutation, others believe that changes in the different levels of a characteristic would be distributed proportionally in the population, being maintained by frequency-dependent selection, among other forms. All of this is part of the same belief that the environment, especially the social environment, is somehow responsible for these differences. This understanding is widely accepted in research on humans and is gradually being explored with non-human organisms (Bridger et al. 2015). In general, what can be perceived is that the development of certain personality traits entails behaviors that may or may not cause harm to oneself or others. In this way, the relationship between personality and crime is palpable.

Crime and Personality

As mentioned before, several theories of criminology use the personality to explain criminal behavior (Akers 2017; Bonta and Andrews 2016; Gottfredson and Hirschi 1990). Since the first studies related to antisocial behavior, it has been possible to verify the strong relationship with the personality. However, the methods used to investigate this relationship have not accounted for the complexity of the phenomenon. Among the methodological weaknesses presented in these studies, the obscure definition can be highlighted of what would be the personality and validity of the instruments used for the evaluation of this construct. Subsequently, a confusing definition generates unreliable instruments (Brown 2015).

Theories that use the personality as key are prone to error, resulting from the use of large and multidimensional constructs such as “antisocial personality” and “psychopathy” (Brown 2015). Although these are correlates of antisocial behavior, their complexity is not covered by any theories, leaving several elements without explanation of their relation to criminal behavior. On the other hand, some theories indicate clear elements of the personality that would be associated with antisocial behaviors. Faced with this, some of these elements are presented, as we seek to highlight their relationship to crime.

However, before discussing the variables, it is necessary to emphasize that crime is a phenomenon that is presented in different ways and that has an intrinsic relationship with cultural issues. In this way, some crimes are explained by a certain set of variables, whereas another crime is explained by others. The purpose of this topic is to introduce the reader to the relationship between personality and crime, in its widest sense. For a specific type of crime, we recommend reading other topics in this encyclopedia such as “Rape (Evolutionary Forensic Psychology)” and “Assault and Murder.”

Among the various theories of personality, the Big Five model was one of the most widely used in the investigation of the most diverse phenomena, and with criminal behavior this would not be different (Allik and McCrae 2002; Bonta and Andrews 2016). In studies that relate this model

to criminal behavior, it is possible to observe a low level of agreeableness and conscientiousness in individuals who have committed some type of crime (Brown 2015; Walters 2018). Other studies also indicate that a high score in neuroticism would also be related to crime; however, this relationship is observed less frequently (Mishra et al. 2017). What can be perceived from the studies that use this model is a certain inconsistency in the results as many investigations explore specific crimes.

As stated, personality seems to influence in some way the type of crime in which an individual engages. This is not a clear and direct relationship as social elements and circumstances are fundamental for someone to commit a crime. However, the Big Five seem to interact with other personality elements, which in turn seem to establish clearer relationships with criminal behavior. In this way, the question “what features of the Big Five would explain more or less of the crime?” is still open, which until today has received different answers. The most correct statement to make about it is that it depends. It depends mainly on two elements, the first one is the type of crime requiring explanation and the second is the context in which this crime occurs.

Despite the disagreements about the relationship of the Big Five with crime, some other personality elements are extensively investigated and rely on several empirical research studies to indicate their relationship. When talking about crime, especially in research investigating opportunities and violent crimes, self-control appears to be one of the main explanatory variables. Since the publication of *A General Theory of Crime* (Gottfredson and Hirschi 1990), low self-control has been at the heart of criminology investigations, as one of the causes of delinquency and crime. The argument is that individuals who have low self-control tend to seek short-term reward, without taking into account the long-term consequences of their behavior. Thus, driven by a search for immediate rewards, individuals engage in criminal behavior.

What draws attention to this explanation is the origin of this low self-control, which according to the authors is the result of socialization, especially

that established by parents (Gottfredson and Hirschi 1990). Parental monitoring during childhood coupled with effective disciplinary practices has long been the main explanation for low self-control. However, some researchers have begun to present other elements that can be aggregated in this explanation, such as school socialization, peer groups, in addition to neural, biological, and genetic underpinnings (Meldrum et al. 2018). Generally speaking, the search for immediate rewards would lead to a person being impulsive, risk-seeking, physical, self-centered, short-sighted, and having a volatile temper, and as a result, they would end up engaging in criminal behavior.

Another personality element linked to criminal behavior is sensation-seeking, which is defined as “the seeking of varied, novel, complex, and intense sensations and experiences, and the willingness to take physical, social, legal, and financial risks for the sake of such experience” (Zuckerman 1994, p. 27). Most studies that investigate sensation-seeking adopt adolescents as participants, because until the beginning of adulthood various structures, neurological and cognitive, are still in formation (Shulman et al. 2015). Individuals with a high sensation seeking may engage in criminal behavior more easily when compared to those who have low sensation seeking. However, this relationship is not established in a simple way; it involves other elements of the personality, among them, impulsiveness.

Like sensation-seeking, low control of impulsivity is related to risk-taking behavior, such as the use of drugs, gambling, online gaming addiction, reckless driving, extreme sports. From risky behavior to criminal behavior there is a space that many texts do not address in which the complex relationship between personality and crime is present. Having a great desire for sensation-seeking and low control of impulse can explain the an individual’s taste for extreme sports, but cannot alone explain why an individual performs an armed robbery (Mishra et al. 2017).

As present earlier, the linear explanation of crime only through personality variables tends to fail, precisely because it fails to account for the complex interplay among them. At this point,

especially for the two variables presented above, sensation-seeking and impulsivity, evolutionary theory offers an explanation for engagement in criminal behavior. Again the search for resources and reproductive success seem to be the keys to understanding these two phenomena. Theories of sexual selection argue that males engaging in risky behavior indicate that they are able to provide resources and protection. Thus, to achieve a higher social position, and consequently increase the chances of reproductive success beyond resources, males would be involved in risk behaviors, and even in criminal behavior, such as homicide and robbery (Shulman et al. 2015).

This hypothesis accounts for other characteristics of the sensation-seeking, such as the fact that men tend to present a higher level of desire for this than women and the fact that it decreases in early adulthood (Zuckerman 1994; Shulman et al. 2015). In the first case, the literature indicates that a great desire for sensation-seeking in women, and consequently engaging in risk behaviors, causes a decrease in reproductive success; thus, there are no evolutionary advantages in this. In the second case, one of the possible explanations revolves around the stabilization of social status, as this seems to be experience-sensitive. In this hypothesis, some of the elements mentioned in the literature can be anchored, being protective of criminal behavior, such as marriage, children and formal employment, as the situation now requires the individual to have a less impulsive and safer behavior pattern to guarantee security and the level of resources.

In addition to these variables, some personality disorders are used as correlates of crime, such as antisocial personality disorder (ASPD) and psychopathy (Bonta and Andrews 2016). Criminology seeks to investigate the relationship between criminal behavior and possible psychopathological conditions that can increase the risk of engaging in criminal behavior. Just as in the cases of people without disorders who commit crimes, cases in which the individuals have some diagnosis of psychological disorders are complex and have multiple causes. However, depending on the disorder, it is possible to verify the incidence of certain crimes. In the case of ASPD, it is possible to observe a

greater frequency of violent crimes, such as aggression and homicide (Shepherd et al. 2018). This disorder is one of the most frequently investigated because of its prevalence in the prison population of several countries (Newbury-Helps et al. 2017).

In general, the pattern of behavior of individuals with this disorder tends to violate the rights and social norms, and this characteristic emerges in childhood with continuation in adult life (Black 2015). In addition, characteristics such as great impulsiveness, lack of security, the tendency to lie, among others, make up the ASPD framework, these being risk factors for engaging in risk behavior (APA 2013; Newbury-Helps et al. 2017). These same characteristics can be observed in another disorder, psychopathy. However, it is important to highlight that this presents other criteria for diagnosis, such as shallow affect, callousness, and an absence of empathy (DeLisi 2018; Hare 2003). Most psychopathic offenders satisfy the ASPD criteria; however, the opposite is not true (Black 2015; Shepherd et al. 2018). The relationship between mental disorder and criminal behavior is established in such a way that various diagnostic tools are used as indicators of risk of recurrence (Bonta and Andrews 2016). One of the main instruments is the Psychopathy Checklist–Revised, developed by Hare (2003) and used in several countries for predicting crimes (Gardner et al. 2018).

Conclusion

Criminology has already been associated with studying ways to explain criminal behavior. It has often been focused on social and contextual issues that could explain certain actions; however, the study of variables related to personality that could be connected has not been neglected. Personality, in turn, presents several explanatory theories of psychoanalytic, psychometric, and evolutionary biases.

In this sense, psychology contributes greatly to the advancement of studies of criminal behavior, and it is dedicated to exploring individual characteristics that can lead to crime. As discussed throughout the text, there are several aspects of personality that may be associated with engaging

in crime, such as impulsiveness and sensation-seeking. In this sense, evolutionary psychologists argue that the resources and evolutionary success may be found in the explanatory basis for cheating behaviors, for example. However, it is prudent to consider that, despite personality and crime characteristics, criminal behavior is emitted because of a complex combination of elements, involving, among other things, individual, social, and cultural aspects.

Causes of criminal behavior; Criminal behavior; Criminology

Definition

For evolutionary studies, criminal behavior is not only a conglomeration of psychological and individual aspects but a complex integration between distinct variables, with explanations involving the past and the present.

Introduction

Crime is multifaceted, with manifold causes, and requires a multilevel analysis to be understood. Essentially, humans' actions have multiple causes, and are influenced by macro and micro aspects that increase or decrease the chances of behavior (Durrant and Ward 2015). Considering that we observe and interpret the world as an ordered sequence of occurrences, what has happened previously reflects on current events. However, the causes are not linear (*a* causes *b*, which in turn causes *c*), which can be seen as a conglomerate of variables affecting nature, society, and

thus human behavior, in a feedback pattern (Bonta and Andrews 2016). Social and individual aspects are present in a complex circular explanation, that involves the past and the present, to make the crime occur.

Criminology is the area of science area investigates crime, searching for scientific explanations for the behaviors that violate social norms. In this field, numerous theories with this goal can be found, with diverse focus, epistemological bases, and methods (Akers 2017; Bonta and Andrews 2016; Durrant and Ward 2015). As there are many theories, the terms describing criminal behavior are varied. Antisocial behavior, offense, delict, among others, are used in the field of criminology to refer to the violation of the social norms and law (White et al. 2017). Thus, in this topic, the general term “crime” will be used as shorthand to refer to all elements explored by criminology.

In addition to the various terminologies used in referring to this field, there are several theories that seek to understand why individuals become involved in crime. Among the current explanatory theories about committing crimes are the Chicago School, Differential Association Theory, Anomie Theory, Labeling Approach and Critical Theory (White et al. 2017).

Crime theories usually elaborate assumptions about human nature, which, in general, are not articulated, considering man, for example, as essentially altruistic or selfish and self-oriented. On the other hand, criminological theories also affirm that human actions, including criminal behavior, would be expressly produced from the individual's relationship with the environment and with others (Durrant and Ward 2015).

In fact, explanations for criminal behavior generally focus on immediate factors, such as the psychological characteristics or the social context in which the individual lives (Akers 2017). On the other hand, despite the relevance of these theories for the administration and control of crime, the evolutionist approach focuses efforts on more distant causes from evolutionary history (Durrant and Ward 2015). It is believed that the integration of distal explanations and proximal explanations of the crime contributes to the elaboration of an explanatory framework of human nature, aiding in

the understanding of crime (Shryock and Smail 2011).

Distal Explanations for Crime

As presented by Duntley and Shackelford (2008), the crime, especially violent crime, reflects the conflicts between individuals. The authors suggest that the crime might have been favored by natural selection owing to the resource advantage to the offender. However, the sense of collectivity, which maintains the social structure, is also favored by evolution, in view of that the chance of group survival is increased when all members cooperate (Duntley and Shackelford 2008). In this context, those who not cooperate, or show behavior that infringes the group norms, are punished (Durrant and Ward 2015). In this way, evolution selects both altruism, which results in cooperative groups, and punishment, to guarantee social organization, in response to crime.

In this context, behavioral scientists have more than one way of understanding the evolution and adaptation of criminal behavior, and these ways are not necessarily exclusive (Durrant and Ward 2015). Among these methods of perceiving the mechanisms that seem to sustain the crime, two are highlighted. The first mode consists of crime as a direct product of evolution, favored by natural or sexual selection, as individuals who commit crimes end up raising more resources by increasing the chances of transmitting their genes (Duntley and Shackelford 2008). However, it is important to emphasize that this strategy seems to be currently at a disadvantage, given the way in which society responds to crime, with more precise methods of investigation and more effective punishments, leading to a decrease in crime rates, especially violent crimes (Bonta and Andrews 2016).

From this point of view, three explanations for crime can still be observed; again, they are not mutually exclusive, all being used in the research carried out in criminology (Durrant and Ward 2015). The first indicates that the adaptation would have worked in the best way possible, favoring criminal behavior. The second explanation expands on the understanding of crime by bringing

to the analysis the context in which it is observed, that is, the mechanisms underlying criminal behavior could also be the result of conditional adaptations that manifest in some individuals in a very specific social and ecological context. Last, the third explanation argues that it would be possible for criminal behavior to have been sustained by adaptations maintained by frequency-dependent selection, with criminal behavior being maintained in a reduced number of individuals in a population.

The second mode of understanding criminal behavior comprehends it to be a by-product of evolution (Durrant and Ward 2015). In this way, the adaptation of another mechanism would favor criminal behavior as a collateral effect. In this approach, the adaptation would be operating as it would have been; however, the crime would be a by-product of this adaptation. Moreover, another possible way of understanding the criminal behavior as a by-product would be that it would actually arise because of a pathological functioning of adaptation. However, it is important to highlight that this mode of understanding and explaining the crime assigns little importance to the context into which the subject is inserted.

Since the adoption of one of these explanations does not encompass the whole phenomenon, it is possible to think that certain crimes would have their mechanisms favored. The division of the specificity of crimes is common in criminology, the majority of authors classify crimes into two major categories, the “violent” and “non-violent” (Bonta and Andrews 2016; White et al. 2017). When the evolutionary explanations for these two categories of crime are observed, it is possible to perceive that the development of both categories travels different paths and is influenced by cultural elements to a greater or lesser degree.

Two concepts are central to understanding these crimes, and in a general way, the aggressive behavior, the notion of aggression and violence. Aggression is understood to be all behavior directed at hurting or injuring another living being (Allan 2017). Aggression is observed in many species of animals, for example, chimpanzees, mainly males, use aggression in diverse contexts, from competition with other males, to obtaining status and resources. Females also exhibit aggressive behavior, but less frequently (Campbell 2015).

The evolutionary logic behind the aggression is clear: it indicates that in any context of dispute (for resources, territory, power, etc.) the use of physical force will constantly be a reasonable strategy that can lead to an increase in reproductive success (Allan 2017). Another aspect is the ability to resist aggression, which also increases the chances of reproductive success, implying a greater transmission of this characteristic. Considering the boost in chances of survival and reproduction, biologists state that there seems to be a specific mechanism for the selection and adaptation of aggression (Durrant and Ward 2015). However, it is important to highlight that this strategy is considered potentially costly, seeing that the results lead to possible harm to the aggressor, who could be seriously hurt or killed. Any organism that consistently engages in violent behavior for a long period has fewer chances of survival (Campbell 2005). In the same way, even with a selection and adaptation process leading to aggression, it is sensitive to individual aspects (age, gender, physical conditioning, etc.) and contextual aspects (resources, social context, etc.) (Allan 2017; Campbell 2015; Durrant and Ward 2015).

On the other hand, violent crimes can be defined as those in which the offender aims to use aggressive behavior with the purpose of causing great injury to the victim (Loza 2018). By this logic, although robbery could be classified as aggressive behavior, homicide is classified as violent behavior. In addition to aggression, the violence can be observed in different species is also influenced by contextual and individual elements. The evidence points to violence also having undergone a specific process and selection in our species. Seeking to understand this phenomenon, Duntley and Buss (2011) proposed a theory that claims that homicide, violent behavior with greater lethality, went through a specific selection process. This theory became known as the homicide adaptation theory (HAT).

According to the HAT, humans possess specific psychological mechanisms for killing, which were selected because of the reproductive advantages that the ancestors obtained. The capacity for homicide would prevent humans from being the victim of possible violent behavior and would provide a certain reputation, guaranteeing social status and consequently security of territories,

resources, etc.. It would also allow the individual to eliminate those within the group considered costly individuals who are not genetically related, in addition to those who are relatives, but who do not present satisfactory conditions for the transmission of genes, such as children with disabilities, individuals with chronic diseases, etc. (Duntley and Buss 2008).

Even showing an reasonably valid argument, the HAT has many critics; some authors do not consider to be the best evolutionary explanation for an understanding of homicide (Durrant 2009; Durrant and Ward 2015). These authors agree with the idea of the mechanism of transmission of the capacity to kill; however, they disagree that the capacity to kill individuals of same species has a specific adaptive mechanism. For some, homicide would appear to be a by-product of the mechanisms of aggression and violence.

Distal explanations seem to be more relevant in the comprehension of aggressive and violent behavior and by consequence the crime in our sciences (Durrant and Ward 2015). Moreover, the distal explanations indicate, with strong evidence, that men are more likely to present physical aggression than women, this being observed in different cultures, historical periods, and at different stages of development (Campbell 2015). This difference between the sexes, which is an important subject in criminology, is greater when there is greater potential for lethal behavior, such as homicide. This difference could be due to a great evolutionary advantage received by men, whereas women would receive a disadvantage, in using physical aggression as a strategy to achieve their goals (Durrant and Ward 2015). However, the difference between men and women is smaller when compared with anger or indirectly aggressive behavior. This, because it does not entail so much damage, appears to be frequent in both, and presents similar advantages to other aggressive behaviors.

Explanations for violent and non-violent crimes work for a variety of criminal behavior, but some crimes are more effectively explained when other mechanisms are involved, such as sex crimes, white collar crimes, terrorism, etc. Considering the purpose of this topic, the distal explanations of all these crimes will not be presented; however,

for more detail, we suggest reading Bonta and Andrews (2016) and Durrant and Ward (2015).

Along these lines, the mechanisms behind the main categories of crimes were presented. In these explanations there are no arguments that individualize criminal behavior, that is, for each of the evolutionary mechanisms presented to explain the crime, the offender is not considered to be destined to commit crimes. From the distal point of view, there are mechanisms underlying the crime that were selected because they present advantages, but all species would, from this point of view, have the same chance of committing crimes (Durrant and Ward 2015). In this way, what differentiates between a criminal and a non-criminal, is precisely the specific, individual, and contextual aspects, which are mentioned in several theories. Thus, the following section discusses the individual aspects related to the crime.

Proximal Explanations for the Crime

Many researchers in criminology are looking for variables that can be classified as “increasing” or “decreasing” the risk of engaging in criminal behavior. More recently, the organization of risk and protective factors for the crime has been more organized and accurate (Singh et al. 2018). Studies that have a focal point in recidivism have spearheaded this field, primarily motivated by programs with the goal of reducing the risk of a return to committing crimes (Bonta and Andrews 2016). Several terms are used to refer to these variables, which can provoke some misunderstanding. Static and dynamic factors, risk and protective factors, criminogenic needs, among others, are terms easily found in research related to crime. In the end, all mention variables relative to criminal behaviors, but each one of them maintains a certain particularity.

Static and dynamic factors are related to the possibility of modifying a certain condition in relation to the individual (Ward 2016). In this way, static factors cannot be altered, e.g., an example of historic antisocial behavior or the fact that one or more members of the family has committed a crime, among others. On the other hand, dynamic factors would be those that can be modified, such as the relations that the person

establishes, their beliefs about crime, patterns of personality, etc. (Bonta and Andrews 2016; Ward 2016). At first glance, these look like “protective factors”; however, the first is about the increase or decrease of the chances of engaging in criminal behavior, whereas the second is about the capacity of modification of those variables. The group of factors considered dynamic can still be called “criminogenic needs.” This term refers to the essentially individual or social characteristics, related to criminal behavior, which when modified or managed at some level, cause a reduction in recidivism (Bonta and Andrews 2016).

Several theories and models of criminology use the risk and protective variables to understand and intervene in the crime (Singh et al. 2018). To this end, some empirical investigations have been undertaken with the goal of assessing the predictive power of those variables in criminal behavior. The main advances in this area come from longitudinal research, considering that they allow us to observe the social and individual changes that individuals undergo (Farrington 2015). Presented here are some variables considered risky, dynamic, and static, referring to most crimes. In the same way that it was possible to identify these variables, the studies also pointed out the effect of specific variables under certain types of crimes, such as sex crimes and white-collar crimes (Beech et al. 2015). As stated earlier, the purpose of this topic is not to discuss all types of crime, but to introduce the reader to this field. Reading Ward (2016) and Singh et al. (2018) can help further in understanding how these variables relate to specific crimes.

Much research classifies different risk and protective variables in criminal behaviors. This distinct allocation occurs according to the theory used by the author, in addition to the resources available for carrying out the research (Bonta and Andrews 2016). Our goal is not to explain each of these variables in detail, but to present this way of explaining the crime. The use of these variables in treatment programs has resulted in reduced crime rates, whether in adolescents or in adults (Singh et al. 2018). The results indicate that in fact these variables have an influence on criminal behavior, but they fail to explain their interaction. Among several groups of variables available in the

scientific community, we highlight the model risk need responsivity (RNR), which shows eight variables to be most explanatory of criminal behavior (Bonta and Andrews 2016).

The spotlight on RNR is due to the method used for its development. The authors conducted a series of meta-analyses, with data from various research from around the world. Thus, a history of antisocial behavior, antisocial personality patterns, antisocial cognition, association with deviant peers, family circumstances, schooling, work, leisure, and abusive use of substances, have been indicated as potential risk factors in behavioral engagements (Bonta and Andrews 2016).

However, the RNR is not the definitive model, or group of variables, in criminology. Several other variables that are not included in it have been presented by other surveys. Research has pointed to adolescence as the period when humans commit more crimes. The relationship between age and crime is bell-shaped, and the first to discover this was Quetelet (1833). The shape of this curve changes according to the type of crime, sex, and socioeconomic conditions. However, even with these differences, adolescents are more likely to commit crimes. Faced with this, criminology has sought to explain why some adolescents engage in crime and no longer do so when they are adults, whereas others continue to commit crimes.

Although the use of risk and protective variables by theories and models is common in criminology, this use is not exempt from criticism (Ward 2016). Some authors argue that the simple use of these variables in the explanation of crime, without worrying about understanding how the interaction occurs, can lead to a dead end (Durrant and Ward 2015). This situation is a product of the researchers' concern in the area of criminology in developing risk assessment tools to predict criminal behavior, regardless of the relation of variables in the real world. The risk factors described in the literature seem to be products, or by-products, of evolutionary mechanisms (Durrant and Ward 2015). Consequently, the explanation of crime assumes macro and micro dimensions, in which the proximal and distal factors interact. Thus, it is possible to explain why two individuals behave in different ways in the same context.

Conclusion

Despite the various ways of understanding the formation of criminal behavior and its evolution, explanations based only on evolution are not sufficient to encompass the whole subject. Consequently, although personality aspects have helped to advance research in this area, they do not provide an adequate explanation of criminal behavior either. Therefore, it is prudent to conceive of crime as a product of evolution without neglecting aspects related to culture.

For a time, criminology has focused on psychological characteristics to explain criminal behavior. Evolutionary psychology has presented advances in this field. In fact, it is possible to understand that a diversity of connected factors lead to criminal behavior; they are related to the evolutionary history of the human species, in addition to the current contingencies of the individual's life. Therefore, there is more than one way of understanding the evolution of criminal behavior.

Definition

Criminology is an interdisciplinary field of study that focuses on crime and the responses to crime.

Introduction

As the study of crime and society's responses to it, criminology is an interdisciplinary field that brings together scholars, clinicians, and other professionals from all types of disciplines to seek an understanding of some of the behaviors that have deep and broad consequences for society. How has crime been studied in the past? How has it been conceptualized by different societies? Why are there inappropriate (i.e., criminal and illegitimate) codes of conduct in all societies where documentation exists? These are some of the questions we will pursue in this entry. First, we will describe what has been studied under the umbrella term "criminology," giving us an appreciation of the history of the field. Then, we will explore some of the more prominent theories in criminology from classical to critical perspectives. Then, we launch into an evolutionary explanation of why criminology exists as a field by framing what it studies – crime and the regulation of appropriate conduct – as evolutionarily relevant phenomena. We then examine how criminological observations of sex and age as important predictors reflect evolutionary principles and expectations of important predictors. Following this example, we more explicitly describe two prominent evolutionary models that attempt to frame criminological issues using evolutionary perspectives. Lastly, we give a brief overview of two varying criminal justice system approaches that frame the issue of *responses* to crime differently – rational-based approaches and honor-based approaches.

What Is Criminology?

Criminology is a field primarily interested in acts constituted as crimes and the subsequent social responses to these criminal acts. Though

sociological theories have played a prominent role in the development of the field of criminology, it is an interdisciplinary field organized around the study of law and crime, incorporating contributions from other disciplines such as psychology, anthropology, political science, and law (Durrant and Ward 2015; White et al. 2018). While there has been a general consensus among scholars and researchers that criminology should include the study of law, the causes of crime, and the responses of society (including responses by citizens, criminal justice professionals, and institutions) to criminal acts, there continues to be disagreement regarding what should be considered a crime and what specifically should be included under the purview of criminology (Durrant and Ward 2015; White et al. 2018).

The most fundamental definition of crime is any action that has legal consensus of being wrong or harmful, that is codified by law or legislation, and that has prescribed sanctions by the state for violation (Agnew 2011; Durrant and Ward 2015; White et al. 2018). That being said, criminologists have also recognized that what constitutes a crime is socially constructed and changes based on historical, cultural, and social conditions (Durrant and Ward 2015; White et al. 2018). For example, cannabis was initially criminalized in the United States in 1937; however, in recent years, many states have changed their laws to legalize the consumption of cannabis for both medicinal and recreational purposes (Adrian 2015). Therefore, many criminologists have argued that focusing on legal definitions of crime is "both too narrow and too broad" in that "it excludes many harmful acts while including many that result in relatively little or no harm" (Durrant and Ward 2015, p. 2). As an alternative, some criminologists have argued that the focus of criminology should not be crime as it is defined by the law but should also include other acts that draw social disapproval or nonlegal sanctions (e.g., ostracization) (Agnew 2011; Durrant and Ward 2015).

Hagan (1987; as cited in White et al. 2018) proposed different dimensions that could be used to define crime. In addition to the legal definition

of crime, he proposed that the definition of crime could be expanded to include social harms (i.e., causes harm to another individual), cross-cultural universal norms (i.e., patterns of crime observed across different cultures), labelling (i.e., actions that are labelled criminal, and are treated as such), and power dynamics (i.e., reflect unequal distribution of power and access to resources within a given society) (Hagan, 1987; as cited in White et al. 2018). Similarly, Agnew (2011) suggested that crime could be broadened to “acts that cause blameworthy harm, are condemned by the public, and/or are sanctioned by the state” (p. 187). While these theorists may differ regarding what to include in definitions of crime, they agree that legal definitions of crime do not capture the breadth of acts that can be considered a crime. Furthermore, while Agnew’s (2011) conceptualization of crime does not account for some of the important factors identified by sociologists (e.g., power differences between social groups), Durrant and Ward (2015) identify that it enables contributions to criminology from other disciplines, including evolutionary sciences. They identify that by advancing the definition of crime beyond legal forms of crime, it opens the field to include acts that threaten *biological fitness* and violate social norms in noncriminal ways, such as bullying or sexual harassment (Durrant and Ward 2015, p. 3).

Establishing an inclusive definition of crime is an important task in criminology given it will help to contribute to a more holistic and comprehensive understanding of crime and its responses. Scholars (e.g., Durrant and Ward 2015; Wright and Cullen 2012) have suggested that the study of crime could be improved if the field of criminology incorporated evolutionary sciences as a means of understanding “the more distal causes of criminal behaviour – those that reside in the evolutionary history of our species” (Durrant and Ward 2015, p. 1). That is, there is a greater role that biological sciences, specifically evolutionary psychology, can play in the understanding of crime since it has already made a significant contribution in parallel areas of interest to criminologists (see section on “[Evolutionary Models of Criminology](#)”) and can be integrated

into current criminological explanations to develop a more thorough understanding of crime (Durrant and Ward 2015; Walsh 2000; Wright and Cullen 2012).

Several researchers have identified that evolutionary theories and conceptualizations of criminal behavior have been overlooked in the history of the field of criminology (i.e., Durrant and Ward 2015; Wright and Cullen 2012). Durrant and Ward (2015) suggested that one of the possible reasons for why biological or evolutionary approaches have been avoided is the role they have played historically in justifying oppressive practices based on deterministic views of criminality, such as eugenics and institutionalization. For example, at the start of the twentieth century, many countries (e.g., the United States, the United Kingdom) implemented legislation that promoted the protection of society through the containment and elimination of persons considered *feeble-minded*. These individuals were considered morally defective and responsible for many social problems, such as alcoholism, prostitution, criminality, and poverty (Scheerenberger 1983). These beliefs were based on research, such as the *The Kallikak Family: A Study in the Heredity of Feeble-Mindedness* by Henry Goddard in 1912, which suggested that based on flawed measurements of intelligence, that feeble-mindedness was hereditary and, in turn, recommended the eradication and containment of persons considered a risk for contaminating the population and threatening the prosperity of the state (Scheerenberger 1983).

While historical uses of evolutionary and biological sciences have been used to oppress certain populations in the past and have been understood to endorse a deterministic view of crime, contemporary evolutionary and biological sciences do not condone oppression, and determinism is no longer a tenable position. Wright and Cullen (2012) suggested that criminologists need to move away from old attempts to integrate biological and evolutionary theories into criminology and recognize the role of a *biosocial paradigm of criminology*, which is “interested in genetic variation and tend[s] to focus on traits related to crime and antisocial behavior to understand how much variance in a specific trait can be attributed

to genetic and environmental sources” (p. 245). Durrant and Ward (2015) expand on this point, suggesting that contemporary developments in evolutionary biology and psychology are more aligned with existing criminological theories.

Current Perspectives of Criminology

As indicated in the previous section, criminology is an interdisciplinary field of study, and though its development has been led largely by sociology, it is composed of multiple disciplines identified in the previous section. As the social, historical, and cultural contexts have changed, several different and occasionally competing perspectives of criminology have developed (White et al. 2018). Each perspective attempts to understand crime and the responses to crime by asking different questions, focusing on different factors that contribute to the behaviors of the individual, society, and social institutions, explaining crime using different concepts, and constructing a different framework for analyzing and responding to crime (White et al. 2018). The four most common perspectives of crime are classical theory, positivism, strain theory, and critical criminology.

Classical Theories of Criminology

Prior to the Enlightenment period, codes of law (e.g., the Code of Hammurabi) existed; however, as Cesare Beccaria – an Italian philosopher and politician of the time – pointed out, the interpretation and execution of the law were inconsistent, and punishments were often disproportionately handed out (Hagan and Daigle 2018; White et al. 2018). As such, the social and political movement in the eighteenth century was characterized by the movement from feudalism to a system in which all citizens had rights that were not connected to their class. In addition, many institutions, including the criminal justice system, were influenced by Enlightenment thinkers that argued humans were rational beings capable of the choices associated with free will. Influenced by these philosophers and social thinkers, classical theorist argued that crime was the result of the individual’s choice or as a result of irrational

decisions (e.g., inebriation). In addition, given each citizen was prescribed individual rights, the state was empowered to develop and codify laws to ensure that all citizens are treated equally (Hagan and Daigle 2018; White et al. 2018).

Classical theorists argued that when a crime occurred, it was a violation of the *social contract*, an implied agreement that citizens will forfeit some of their individual rights in exchange for protection from the state. Cesare Beccaria argued that crime impacted all citizens and “society as a whole,” and therefore it was the role of the state to re-establish order (White et al. 2018, p. 28). In addition, philosophers such as Jeremy Bentham argued that all of human behavior could be reduced to the pleasure-pain principle that humans act in ways to maximize pleasure and to reduce pain. Therefore, classical theories of crime focused on punishments that were not vengeful but that acted as a deterrent to prevent both the individual from committing another criminal act and other citizens from committing offenses. Therefore, the role of the state was not only to decide what constitutes a crime but also what punishment was proportionate to the crime (Hagan and Daigle 2018; White et al. 2018). That is, by calculating the cost-benefit ratio of acting criminally, the state could ensure that the set punishment was painful enough to act as a deterrent and would nullify the reward for acting criminally.

While classical theories of criminology have been largely influential in many international criminal justice systems, critiques have identified that the law remains unequally distributed among citizens, with some populations being overrepresented. Furthermore, with regard to punishment, proportional sentencing may not be experienced the same by all citizens. For example, persons of lower socioeconomic status are more likely to experience monetary fines as more punitive than a person with more resources associated with higher socioeconomic status (White et al. 2018).

Positivist Perspectives of Criminology

In the nineteenth century, ideas regarding the nature of humans were being defined by the colonialism of European nations throughout

the world and the development of the natural sciences using the scientific method. Positivism developed as a way of understanding how the world worked and “ultimately provid[ing] a rational means of overcoming existing social problems and ills by using the scientific method” (White et al. 2018, p. 38). Criminology was no exception to this rule – how could the scientific method and a new understanding of the world (e.g., evolution) be used to understand crime and provide an effective response to crime? Two areas of interest become of interest to positivists: the individual differences that contributed to an offender deviating from the general population that caused crimes to happen and social contributions – mechanisms within society (e.g., the family unit) that no longer operated to ensure the “system was working as a whole” (White et al. 2018, p. 39).

Compared to classical theorists who focused on the law and the nature of the offense, positivists focused on the offender and the individual and social characteristics that contributed to the offense (Hagan and Daigle 2018; White et al. 2018). This shift in focus had a significant impact on the definition of crime, since it no longer focused strictly on legalistic aspects of crime but began to include deviations from the norm (e.g., mental illness, deviant social roles). One of the most well-known positivists was Cesare Lombroso, an Italian physician, who tried to categorize people based on Darwin’s theory of evolution (Hagan and Daigle 2018; White et al. 2018). He initially proposed that criminal behavior was the result of *atavism*, a regression to an earlier stage in human evolution; however, he later refined his classification to different typologies of the criminal (Lombroso 1911; White et al. 2018). For example, he suggested that female offenders were typified by characteristics traditionally ascribed to men.

Given the deterministic perspectives of the positivist criminological theorists, it is unsurprising that the responses to crime were limited (Hagan and Daigle 2018; White et al. 2018). While classical theorists emphasized the importance of sentences that suited the crime, positivists tended to recommend an indeterminate sentence that took into account the characteristics of the

offender. In addition, positivists focused on interventions such as treatment or containment to prevent further disruption to society.

Critics of positivist theories have identified that these theories have limited ability to explain all crimes (e.g., white-collar crime). Furthermore, as stated previously, many of these theories were misappropriated and used to oppress many populations (e.g., racism). Finally, it has been criticized for focusing too heavily on the individual and micro-level contributions (e.g., familial trauma) to crime and not accounting for macro social conditions that also contribute to criminal behavior (e.g., poverty) (Hagan and Daigle 2018; White et al. 2018). Nevertheless, some contemporary writers still ascribe positivist interpretations to criminal conduct (e.g., Raine 2014).

Strain Theories of Crime

With the development of sociology as a discipline and international changes following World War II observed in the twentieth century, criminologists became more interested in the distribution of opportunities throughout society, the ways individuals related to each other, and the impact of these variables on crime (White et al. 2018). Strain theories of crime were the first sociological theories of crime, which suggested that crime was a social phenomenon and the product of social processes and structures. While positivist theories of criminology assumed that crime resulted from individual deficits, strain theorists believed that crime represented a violation of social norms – the agreed-upon values and behaviors within a society (White et al. 2018). That is, crime was not a result of individual deficits or pathology but the result of social strains or tensions (Hagan and Daigle 2018; Walsh 2000; White et al. 2018). Strain theorists proposed that when citizens do not have equal access to resources (e.g., wealth), these individuals will seek out alternative, inappropriate opportunities to meet their needs. For example, Sampson and Laub (1993) examined how race and economic opportunities shaped the experiences of African-American youth being charged with an offense. They found that the experiences of African-American youth were indeed characterized by poverty, which in turn

influenced their confinement, especially when being charged with a drug offense.

One of the most influential strain theorists was Émile Durkheim, who proposed that crime was the result of *egoism* and *anomie* (White et al. 2018). Egoism is the state of society characterized by excessive individualism – “the unrestricted pursuit of individual desires;” whereas, anomie is “a state of normlessness, in which society fails to impose norms that inhibit such behavior” (White et al. 2018, p. 76). The importance of Durkheim’s contributions was that it drew attention to the fact that crime was the by-product of certain types of social order (White et al. 2018). Merton (as cited in White et al. 2018) further contributed to the idea of anomie by suggesting that crime could be understood in relation to two main variables – cultural goals shared by all citizens (e.g., wealth, status) and the different institutional means of achieving these goals. He proposed that “depending on the opportunities available to [citizens], people decide to accept or reject the cultural goals and to accept or reject the institutional means to attain commonly accepted goals” (White et al. 2018, p. 80). Merton would have argue that the youth in the Sampson and Laub (1993) study experienced greater barriers to accessing resources, which in turn influenced the decisions they made.

Strain theorists proposed that crime is best addressed by combining individual rehabilitation with institutional reform that increased access to social programs (Hagan and Daigle 2018; White et al. 2018). They recommend removing causes of strain by increasing access to social programs that target citizens at risk of experiencing strain (e.g., job finder clubs or afterschool programming) and that reduce the strain experienced by these individuals (Hagan and Daigle 2018; White et al. 2018).

Critical Perspectives of Crime

Finally, critical theories of crime are concerned with the structures of power within society and the ways that power is institutionalized to privilege certain groups of citizens. For example, critical feminist criminologists are concerned

with the ways that the law and the criminal justice system are structured so women face oppression. Thus, many critical criminologists concern themselves with revealing the underlying power dynamics that structure how different groups of citizens are treated and finding solutions to address them (Hagan and Daigle 2018; White et al. 2018).

White and colleagues (2018) identified that critical criminologists can be divided into two theoretical orientations – *structuralists*, who focus on power as something that is embedded in social institutions (e.g., the criminal justice system), and *postmodernists*, who examine how “knowledge production shapes human experience while simultaneously engendering conflict over meaning” (e.g., prostitute vs. sex trade worker) (White et al. 2018, p. 233). While structuralists view the marginalization of some social groups as the cause of crime, postmodern approaches identify that dominant discourses or popular beliefs are responsible for establishing what is a crime. Both structuralists and postmodernists are interested in revealing the underlying power relationships that contribute to the experiences of different social groups within the criminal justice system; however, structuralists focus on empowering disenfranchised groups and redistributing resources equitably, and postmodernists focus on building an inclusive society by defusing the power of dominant beliefs about criminalized groups of individuals (White et al. 2018).

While all of these perspectives have advanced the field of criminology, Durrant and Ward (2015) identified that evolutionary approaches have had limited influence in the field of criminology. Furthermore, several criminologists have identified that criminology is still a developing discipline and has yet to provide any solutions regarding how to prevent crime. Durrant and Ward (2015) proposed that the incorporation of the evolutionary approach into existing perspectives may lead to a more complete theory of crime and develop more effective laws and legal structures to address crime. The goal of this chapter is to explore how an evolutionary approach can be used to enhance criminology.

Evolutionary Logic of Criminology

The problems and issues that stimulate a study of criminology reflect both the prevalence and reality of crime in society *and* that there is something about it requiring and capturing our attention. In other words, criminology is not just the study of crime as a static reality in society, it is also revealing of our concern for the welfare of society. Humans are an obligate social species that depend on one another for their survival and well-being, making the idea that we should care about the welfare of society completely obvious. But what of criminal behavior? Why does criminal behavior emerge at all where it can begin to disrupt social welfare? And why do criminals not only face costs associated with their criminal activities but also tend to reap benefits? These are questions that are informed by an evolutionary perspective on criminology and are required if criminology is to maintain a nonarbitrary conceptualization of crime and criminal activity (Durrant and Ward 2012). Here, a nonarbitrary view provides a full explanation of why things are constituted as they are and not some other way and is a unique feature offered by evolutionary thinking for the social sciences (e.g., Buss 2009).

The law is an ever-present and structuring feature of modern societies. It embodies the criminal justice system that determines what constitutes a crime and upholds the law by responding to the commission of such crimes. But where does it come from? Yes, we can track the legal operation and history back to its recent origins in Greek and Roman – as well as other – societies (see section on “[Current Perspectives of Criminology](#)”), but where does it *really* come from? Why is there a law at all? What is it about humans that seem to compel us to create a law? Again, the logic provided by an evolutionary perspective is positioned to generate answers and explanations for these types of questions, suggesting that its inclusion in criminology is not only needed but desirable as well (Walsh and Jorgensen 2018).

The questions posed in the above paragraphs require more expounding. Crime and the law that defines it are concepts fundamentally important to criminology, but why should these things exist?

An evolutionary perspective is able to answer this by conceptualizing *crime* and *the law* as social constructs that reflect humans’ morality – what feels right versus wrong, seems fair versus unfair, and deemed just versus unjust – which constitutes them as an obligate social species shaped by and for these features (de Waal 2008; Haidt 2001). Most criminologists would easily recognize that this is the case that crime and the law are clearly morally infused. However, an evolutionarily minded criminologist appreciates that moral impulses and intuitions form the core of what has come to be called “crime” and the “law” that governs it. They acknowledge that these underlying moral impulses and intuitions have been shaped into us by selection because they have fitness consequences for individuals existing in those social groups. Thus, a deeper, nonarbitrary explanation is offered in using an evolutionary perspective toward problems of criminology, including the very framing of the discipline and its problems.

Another example that shows the nonarbitrary explanation that evolutionary perspectives offer criminology is understanding our different standards of conduct depending on who the victim of the crime is and the context surrounding it (Walsh and Jorgensen 2018). For instance, offenses committed against members of your own community were likely the primordial forms of criminal conduct that warranted punishment and/or correction. These crimes likely included cheating, theft, and assault against in-group members (Durrant and Ward 2012). What is interesting in using an evolutionary lens is that it becomes comprehensible why many societies do not punish acts against out-group individuals that might otherwise be considered criminal conduct. A particularly clear example of this is murder: killing in-group members is considered illegitimate and a supreme form of unacceptable behavior, whereas the killing of out-group members has legitimacy, particularly in the context of war (Daly and Wilson 1988).

Legal documents and codes of conduct have been prevalent in societies for thousands of years going back to Hammurabi’s Code. These codes of conduct, however, regulate the behavior

of individuals *within* a society, making their jurisdiction limited in scope to the group of people being governed. Even societies that do not have written technology abide by codes of conduct that monitor, regulate, and punish the behavior of in-group members not in the same way as out-group members. An example is the Yanomamö tribes in what is now Venezuela and Brazil. This diverse group of tribes strictly regulates and punishes in-group cheating, theft, and assault while condoning and sometimes encouraging out-group displacement and elimination (Chagnon 2013). It is expected that this should be the case from an evolutionary perspective; in-group codes of conduct should form the core of human societies, and out-group conduct should be separate, confined to a separate code of conduct involving intergroup relations. That international law has not become a preoccupation of individuals around the globe until the seventeenth century suggests codes of conduct regarding out-group members has not been as an important feature of how societies regulate wrongful behavior as have the codes of conduct within in-group contexts. In other words, evolutionary logic predicts that human societies should first be concerned with governing their in-group members because this most ostensibly had fitness consequences for the individuals abiding by those codes of conduct, especially in ancestral environments structured by nomadic and foraging conditions (Tooby and Cosmides 1992).

So we have seen that crime and the law reflect our moral impulses and intuitions, and this can be informed by an evolutionary perspective. But the final point to make in demonstrating the evolutionary logic behind criminology, as a discipline and in its subject matter studied, is to show why crime is classifiable as a concept at all. In humans' struggle for survival, status, and intimate relationships, individual desires can often come into conflict with the desires of other individuals within the social group. While humans are clearly an obligate social species dependent on each other, competition for scarce resources abound, especially in our ancestral environments where the traits and features of the mind were shaped (Tooby and Cosmides 1992). Disagreements

involving resource competition can progress to altercations, violence, and homicide (e.g., Daly and Wilson 1988); they can progress to stealing from or cheating a competitor; they can progress to harassment, abuse, and rape. What are these individuals even competing for that makes them so motivated to commit acts that their community will certainly punish? The answer is connected to resources that guarantee, or at least enhance, one's survival and reproductive success. Ancestors equipped with the capacity to engage in these acts – especially in certain contexts signaling unpredictability, harshness, and competition (e.g., Durrant and Ward 2012; Mishra and Lalumière 2008) – would have left versions of themselves more successfully than alternatives that could not engage in such acts given the *appropriate* context. Thus, crime exists because it underlies behavior that reflects the possibility of creating differential reproductive success in the competition for resources and mates.

This begs the question for some people not familiar with deploying an evolutionary lens of why everyone is not a murderous, cheating, thieving, and raping despot? Setting aside the fact that some humans who accumulated enormous and unconstrained power in history fit this bill (e.g., Genghis Khan, Ivan the Terrible), selection pressures have also abounded that shape prosocial, moral, and cooperative traits and features into the human mind. This is why we spent time discussing why crime and the law reflect moral impulses and intuitions. There is something about humans and other social species that demonstrate the survival and reproductive benefits of engaging in prosocial, empathic, and moral thoughts, emotions, and behaviors (de Waal 2008). It is not sufficient to conceive of competition for resources as a prerequisite to optimizing organisms for conflictual and individualistic thoughts, emotions, and behaviors. The benefits for survival and reproduction of engaging in more cooperative acts and forming cooperative networks must be immense; otherwise, they would not have come to structure human societies the way they have, giving rise to codes of conduct, legal systems, and morality (Haidt 2001). Cooperative thoughts, emotions, and behaviors facilitated by our moral

impulses have created a more *sustainable* way to survive and reproduce across generations. Thus, while competitively selfish individuals may benefit immediately and over one generation, this may not be sustainable multi-generationally, making the execution of such selfish and often “criminal” conduct more context-specific and responsive to certain cues in the environment (more on this in later sections; e.g., Mishra and Lalumière 2008). Thus, when cooperating, competition for survival as a group of individuals and as a species can warrant engaging in selfless acts promoting the well-being of the group over the individual. In acting selfless, one may also enhance their own reproductive success in gaining respect, status, and mates.

Especially in contexts where biological kin are prevalent as would have been the case in ancestral environments, selfless acts are often not fully selfless; instead, they reflect investing in reproductive success of closely related kin, suggesting a need to consider inclusive fitness as opposed to individual fitness (Hamilton 1964). Crimes in modern society, illustrated by the example of homicide, illustrate this kin-biased tendency. Estimates suggest around 6% of homicides in the United States involve biologically related victim-offender relationships, with the vast majority involving non-related individuals and a lesser amount involving spouses or friends who are also not related (Daly and Wilson 1988). For infanticide specifically, the risk increases approximately 100-fold when a stepparent is present than when the biological parents are present. These data illustrate the importance of using an evolutionary framework when examining criminal cases for a deeper, fuller explanation of crime and how to respond to it.

Criminological Problems and Evolutionary Principles: The Elusive Cases of Sex and Age

Why are men across cultures responsible for most of the violent, sexual, and even “petty” crime in societies (e.g., Krug et al. 2002)? Why does risk for criminal activity increase after puberty and decline thereafter? These two often-taken-for-granted demographic variables – sex and age – are some of the strongest and most reliable

predictors of engagement with crime (Hagan and Daigle 2018). Existing criminological theories have difficulty explaining the strength and reliability of either of these two variables’ prediction of crime, let alone providing a theory that accounts for and explains both variables’ involvement (Durrant and Ward 2015). Evolutionary principles, however, easily enable a conceptual understanding of both how and why sex and age should predict involvement in crime and, in addition to this, the types of crimes individuals at different levels of those variables are likely to commit (e.g., females vs. males, early adolescents vs. young adults). Evolutionary theory provides this conceptual understanding by examining three interrelated foundational principles that reveal its unique competence in explaining the involvement of sex and age in predicting crime.

The first evolutionary principle is *parental investment asymmetry* (Trivers 1972). The asymmetry here refers to the inherent differences that females and males as potential and actual parents exhibit in the ways they can invest in their offspring. Focusing on humans and other mammals, females are uniquely responsible for gestation, placentation, and lactation; even if males wanted to help with sharing the responsibility for ensuring these needs are met, they could only ever do so from a distance and in providing support for the female to do so (Hewlett and Macfarlan 2010). Males, on the other hand, are more likely to provide parental investment uniquely through acquiring food and other resources and ensuring security against predators and other threats (e.g., from other groups). Fathers, and other sources of social support, are also obviously likely to provide extended care of offspring, especially as children become more mobile and dependent on other sources of food besides breast milk (Hewlett and Macfarlan 2010). To illustrate the profound need of each sex to specialize in raising offspring, just imagine a mother of newborn twins in a foraging society faced with the task of breastfeeding both infants, maintaining social relationships, and gathering sources of food but *also* pressed with the task of finding high-calorie and high-protein food (e.g., hunting) and maintaining land and securing it against potential invaders and

predators. Or imagine a father of a newborn in a similar context whose partner passed away in childbirth. How will the child survive if they cannot yet eat solid food and he has no source of providing breast milk? These mental exercises demonstrate the need of both sexes working in concert on differentiated tasks to raise healthy offspring in the foraging environments of our ancestors (Friedl 1978).

This asymmetry articulates parental investment theory, and as this system reaches an evolutionary equilibrium (i.e., the evolution of mammalian strategies of gene replication), selection pressures would build and maintain this equilibrium. This is all to say that, evolutionarily, it is expected that males and females will be interested by and competent at different tasks, not absolutely but relatively. Criminal activity through this principle should differ based on sex and age. Younger mothers with less certainty about resource procurement and social support should be expected to engage in infanticide at a higher rate if they perceive they will not be able to raise the infant to reproductive age, a finding supported by research (Daly and Wilson 1988; Hrdy 1999). Young men who are not yet fathers are expected to engage in the highest-risk behavior in efforts to demonstrate usefulness and competence to climb the hierarchy of their male peers and appeal to putative opposite sex partners who may become the mothers of their children. This is also borne out in research, with young and unmarried men representing the highest-risk group for committing homicide (Daly and Wilson 1988) and other crimes (Krug et al. 2002).

The second evolutionary principle informing sex and age demographics in crime follows intimately from the first principle. The second principle, *reproductive success-from-multiple mates*, is that there is a reproductive limit imposed on females in mating with multiple partners that is *not* experienced by males (Bateman 1948). Putting aside morality, sustainability, or other constraints imposed upon humans, one man could impregnate many women within a relatively short time span. The same is not true if the women in this scenario had multiple men to

mate with. Women, even if they have multiple male sex partners, will become impregnated during *only one* of those matings, and any matings thereafter would not add to her reproductive success in a straightforward and reliable manner (cf. Hewlett and Macfarlan 2010; Hrdy 1999). This reality imposes selection pressures on the thoughts, emotions, and behaviors of males to be more likely to consider or pursue casual and multiple sexual partners that is not comparably found in females. In this framework, males should be more preoccupied with and engage in casual sex because it was more likely (but not definite) to enhance at least some ancestral males' reproductive success (Daly and Wilson 1988).

How does this second principle influence sex and age demographics involved in crime? Based on this principle, males are expected to engage in riskier, more impulsive, and more sexual thoughts, emotions, and behaviors. This could facilitate the engagement in extra sexual relationships that otherwise would not be acquired; the costs associated with risky and impulsive tendencies is offset by the potential reproductive benefits in males that is not the case for females. Thus, behaviors that involve risk and impulsivity such as showing off in dangerous situations, adventuring to unknown areas, and willingness to engage in anonymous sex are more common in men (Mishra and Lalumière 2008). These noncriminal but "deviant" actions reflect a sex-biased tendency to engage in criminal actions as well, including violent altercations, sexual harassment and assault, and homicide (Daly and Wilson 1988). Thus, the same tendency that may make men reduce their threshold for risky and impulsive actions because of their potential reproductive payoff may form the base for their over-involvement in crimes as well, helping to explain why men and not women are committing most crimes and especially sexual and violent crimes.

The third evolutionary principle of explaining sex and age demographics in crime is *reproductive variance asymmetry*. This principle relies on and follows from the first two principles and states that because women can spend lengths of time caring for existing and not producing new

offspring and men can father multiple offspring with different women, there is a greater likelihood that some men may not reproduce at all while others may reproduce an inordinate amount (Daly and Wilson 1988). This observation of greater variance in reproductive success should be less stark for women because they will have both many potential male partners interested in them and will not experience the same reproductive benefits in seeking out multiple partners (Bateman 1948). This principle observes that men who acquire more resources, dominance, and influence socially may translate their social and cultural capital into having many sexual partners, which subsequently enhances their reproductive success while making other men lose out. This is supported in foraging societies (e.g., Chagnon 2013) and in acute historical examples such as the life of Genghis Khan. Men in these and many other societies left no offspring in the next generation because one or a few men were reproducing with more of the women than a one-to-one ratio would suggest. This observation identifies a hidden anxiety that may structure the reproductive efforts of men, especially when environmental cues suggest the variance in reproductive success is skewed in favor of a few men (Daly and Wilson 1988).

This hidden anxiety and the evolutionary principle fueling it may be powerfully positioned to comprehend both the sex and age disparities in the commission of crime. Why do boys and young men seem so motivated to compete? Why does this competition often fuel violence, abuse, and even fatalities? If the stakes are, or could be, as high as being among the few who reproduce compared to the many who do not, then competition to be among the few could become fierce. Methods to be counted among the few may be stretched beyond “appropriate” limits – stealing to acquire resources, killing to gain status as a fierce fighter, and sexually coercing a woman against her will. As a male reaches puberty and is entering the reproductive pool, this competitive edge and feeling the hidden anxiety of male reproductive variance begin, explaining the age-crime curve that positions adolescent and young men as the most criminal. The important thing to consider with this

principle is that it is the *perception* of boys and young men growing up that can fuel this competitive mentality. If they perceive their environment as competitive where few males are succeeding and most are failing, this may be enough to orient them toward thoughts, emotions, and behaviors that facilitate or at least permit the illegitimate use of criminal conduct. This is why an evolutionary explanation is useful to criminology: it offers a conceptualization useful for formulating social policy that reduces the likelihood of crime by working *with* the desires of youth and, in this case, how to reduce the instance of young men committing criminal acts (see Durrant and Ward 2012; Walsh and Jorgensen 2018).

These three evolutionary principles – parental investment asymmetry, reproductive success-from-multiple mates, and reproductive variance asymmetry – provide a powerful framework for understanding the tendency of sex and age to be predictive of crime across societies. Appreciating not just *that* these variables are predictive but *why* they are as well requires a deeper explanation than what is currently on offer from criminological theories (see section on “[Current Perspectives of Criminology](#)”; Durrant and Ward 2015). An evolutionary perspective adds complementary, and not necessarily competitive, explanation to existing criminological theories and concepts (e.g., Durrant and Ward 2012). We will now turn to more fully articulated evolutionary models that have treated criminological issues as their central focus.

Evolutionary Models of Criminology

The two most prominent models in constructing an evolutionary argument of the problems of crime are life history theory (LHT; for a thorough review, see Del Giudice et al. 2016) and evolutionary neuroandrogenic theory (ENA; Ellis 2005; Ellis and Hoskin 2015). These theories are not mutually exclusive and have more similarities than differences. LHT and ENA are presented so that readers may get a different flavor for how evolutionary theory and its principles can guide research in criminology.

Life History Theory

A unique and fundamental observation made by LHT is that organisms make trade-offs during development in the different areas of growth, maintenance, and reproduction (Del Giudice et al. 2016). This observation brings to light that investment in some areas can preclude investment in other areas, particularly when resources and energy are scarce. Because our ancestral environments (and many modern environments) would have had long periods of resource and energy scarcity (e.g., Tooby and Cosmides 1992), evolution has likely instilled environmentally contingent strategies in organisms that vary the level of investment in these areas of development, leading to manifesting the capacity for what can be called different life history strategies. Fundamental trade-offs that organisms make include assessing current versus future reproduction, quality versus quantity of offspring, and parenting versus mating effort (Del Giudice et al. 2016). The resulting investment is considered an individual's life history strategy, and this strategy represents the embodied capital that an individual has, with the notion of "capital" implying currency in the capacity for survival and reproduction.

LHT proposes that organisms are fashioned within their genetic endowment to respond *flexibly* to their environments depending on different salient and recurrent environmental cues. This flexible responding allows organisms that have faced variable environments over the course of generations to have multiple pathways to ensure reproductive success. Or, different environmental pressures throughout a species history have led to different gene-environment adaptations (and the thoughts, emotions, and behaviors they produce) that facilitated reproductive success. LHT argues that the predecessors of these ancestral organisms have inherited a repertoire of adaptations that are "unlocked" and expressed when similar environments are faced by this new generation that shares this genetic endowment. From this perspective, LHT claims that evolution has "done the thinking" for organisms and provides them with different

developmental pathways that respond to environmental variability to optimize trade-offs in facilitating reproductive success (Del Giudice et al. 2016).

An LHT perspective conceptualizes engaging in criminal and antisocial conduct as representing a strategy that leans toward investment in current reproduction (not future), quantity of offspring (not quality), and mating effort (not parenting) (Wiebe 2012). In this model, investing in specific cognitive, emotional, and behavioral strategies that themselves may not constitute criminal conduct (e.g., anger, impulsivity, future discounting) may lead to increasing the risk of engagement in crime. Strategies that mark more crime-risk calibrations are described as *faster* life history strategies, whereas less crime-risk calibrations are *slower* life history strategies (Boutwell et al. 2015). The environment is a key component in this theory. LHT suggests that children (and even prenatal fetuses) are constantly monitoring their environments for cues that help them make optimal developmental decisions to ensure their survival and reproductive success. Environmental cues that signal unpredictability, harshness, and social competition are proposed to orient development toward more crime-risk life history strategies, making these types of environments important for criminologists to understand. Because of these concerns, LHT is similar to other criminological theories such as strain theory (Durrant and Ward 2012). LHT is one evolutionary framework that provides a unifying understanding of many variables that predict crime including sex, age, race, and socioeconomic status (Boutwell et al. 2015).

Evolutionary Neuroandrogenic Theory

ENA focuses on and provides an explanation of both the *how* proximate mechanisms associated with criminal correlates and *why* such correlates should exist (Ellis 2005). The *why* part of ENA encapsulates the evolutionary component, and the *how* part constitutes the neuroandrogenic component. The two components of ENA are intimately connected and conceptually represent a single

underlying construct formulated at different levels of analysis (Durrant and Ward 2012). The theory makes use of the concept of competitive/victimizing behavior, which describes a continuum of competitive actions that can vary on their risk or chances of victimizing another individual (Ellis and Hoskin 2015). Actions that are competitive but do not have a victim (e.g., competitive sports, games) are not considered criminalized behaviors, but competitive actions with victims are considered criminalized (e.g., sexual assault, theft). It is no surprise that these actions with victims tend to have consequences for survival and reproductive success of both perpetrator and victim.

The evolutionary component of ENA makes use of female mate choice to assist with explaining why competitive/victimizing behavior should exist in the first place and particularly in men. Connecting back to parental investment theory (Trivers 1972), ENA proposes that females have preferred and thus selected for males throughout humans' evolutionary history to be loyal resource provisioners for the successful raising of offspring. This idea suggests that ancestral females would have been more likely to mate with males who were proficient at provisioning resources for her and her offspring, making traits that facilitate resource provisioning more and more common in males. Some of these traits would include competitiveness, status-seeking, and hunting skills, of which men across cultures tend to manifest more than women (Ellis and Hoskin 2015). Along with this observation for more resource provisioning skills in men is the accompanying selection pressure for men to fake these skills and rely on deception to mate and, if deception fails, to potentially resort to coercion. Thus, ENA provides a framework for understanding why the patterns of crime exist and why men tend to exhibit characteristics that make them more likely to be counted among the criminals. How these characteristics get formed is the concern of the other component of ENA.

The neuroandrogenic component of ENA suggests that the way this differentiation of the sexes occurs is through masculinization of the brain and

body through androgen hormones, particularly testosterone (Ellis 2005). This component clarifies that in order for a male reproductive strategy to manifest, changes need to occur in the neural structures governing behavior, which can then facilitate more male-biased strategies. These are proposed to be (1) suboptimal arousal and (2) rightward shift in cortical functioning. These two proximal explanations of making a brain more male-like constitute a higher risk of engaging in competitive/victimizing behavior, since these mechanisms facilitate analgesic (pain-reducing), anxiolytic (anxiety-reducing), and emotion-attenuating functions (Ellis and Hoskin 2015).

ENA provides an explanation of why crime, as behavior that is competitive and victimizing, is more common in men than women and why age, particularly the onset of puberty in boys, predicts crime to such a great extent. With the relative enormous surge in testosterone at puberty in boys compared to girls, ENA clearly conceptualizes why crime increases after this age in boys and young men while also accounting for why this hormone-behavior link should occur to begin with. In other words, the link emerged because of selection pressures for the resource provisioning skills required and desired by females in the ancestral past to ensure the health and survival of their offspring.

Variations in Criminal Justice Systems

In this final section, we want to explore how evolutionary approaches can support alternative forms of justice. Just as criminology has developed, so too has the criminal justice system. While moral impulses and intuitions are expected to structure and guide the formulation and response to crime, humans also have a vast capacity to cognitively rationalize and reason which can impart substantial influence on moral judgments (e.g., Haidt 2001). To illustrate this difference in criminal justice system approaches, we will describe two systems that have different

underlying assumptions about “human nature” and that have influenced how crime and responses to crime are conceived. The first is the current dominant approach in much of the world, a rational-based retributivist and rehabilitative approach, while the second is more prevalent in indigenous communities and likely governed the behavior of much of human history, a relational honor-based system based on reparation (Little Bear 2000; Sommers 2018). We do not intend to treat these systems as oppositional or polarized nor to claim they are the only two possibilities but merely to explore alternative systems for crime and its regulation. Many modern jurisdictions have developed structures that blend these two approaches to justice (for a longer discussion of these systems, see Sommers 2018).

Much of the Anglo-American criminal justice system has developed based on the retributivist principles first introduced by classical theorists (such as Jeremy Bentham). That is, when an offense has been committed, the state is responsible for assessing culpability and imposing a fitting punishment. Once the punishment had been served, justice had been served (Wenzel et al. 2008). Wenzel and colleagues (2008) identified that there were two goals of punishment (1) deterrence, to prevent the likelihood of future offenses, and (2) retribution, a proportionate and just response to reduce the benefits associated with committing crime. Alternatively, another goal of the criminal justice system is rehabilitation of the offender, that is, to address the individual factors associated with the offense to be able to reintegrate the offender back into society (Wenzel et al. 2008). Durrant and Ward (2015) noted that from an evolutionary perspective, “we have evolved a set of motivational and emotional characteristics that, taken together, constitute a sense of justice and guide our decision-making when we encounter situations where individuals have violated moral and social norms” (p. 111). They also noted that people tend to be naturally motivated to punish others who violate group norms in retribution; however, as Walsh (2000) noted, a strict tit-for-tat strategy that is unforgiving once cheated may not garner the same benefits that occasional or situational forgiveness would permit. He

suggested that while tit-for-tat was effective in smaller groups, the addition of punishment is more effective in larger groups.

In contrast to these rational-based systems and their measures of correction, relational honor-based systems may constitute a primordial conceptualization of crime and its regulation, possibly tracing its origins to some of the first foraging societies and many modern indigenous communities (e.g., Little Bear 2000). This approach assumes that human nature is inherently relational and that people are seen as intimate extensions of their social group; the social group is the person, and the person is their social group. Following from these assumptions is that people have an inherent responsibility toward their society and are thus expected to make reparations when infractions against others within the society have been committed. These infractions (or crimes) are seen as relational injustices, and so they require a relational approach when formulating a model for correction and/or punishment.

In recent years, criminologists have started to pay attention to other models of justice that reflect an honor-based system, such as restorative justice. While scholars and advocates continue to debate whether this model of justice represents an alternative or addendum to the current criminal justice system, several legislations have started to incorporate restorative justice principles in their legislation (e.g., the Youth Criminal Justice Act in Canada) (White et al. 2018). Scholars of restorative justice (e.g., Zehr and Mika 1998) have outlined three key tenets of restorative justice: recognition that the offense does not only affect the victim and the offender but also members of the community; recognition that the offender has obligations and liabilities to the community as a result of their actions; and finally, recognition that the process promotes community empowerment and healing.

In restorative justice models, the focus is on reparation – repairing the relationship between the offender, the victim, and the community (Wenzel et al. 2008). While punishment can be part of the restorative justice, it is not the focus of the process. Braithwaite (1989; as cited in Walsh

2000) suggested that a critical process in restorative justice is *reintegrative shaming*, which communicates social disapproval and also provides an opportunity for the offender to make amends and remain a welcomed member of the community. Walsh (2000) suggested that this is akin to the tit-for-tat with forgiveness model, which highlights the importance of forgiveness since they can “transform a pattern of mutual cheating by not remaining permanently punitive but instead by cooperating, even when the other strategy cheats” (p. 857). That is, everyone (victim, offender, and community) benefit from forgiveness and the processes of restorative justice, and the risk of losing a valuable contributor that may help to secure survival is decreased. It is interesting that restorative justice models have been integrated into legislation targeting youth. Walsh (2000) identified that a strict tit-for-tat strategy with youth would be detrimental, especially given adolescence represents a period in which there is a discrepancy between skill and biology.

Conclusion

Criminology is an interdisciplinary study of crime, and the responses to crime have generated a wealth of knowledge surrounding the commission of crime, its predictors, social situations that elicit it, and many other topics. Its inherently interdisciplinary focus makes criminology a prime study for integrating an evolutionary framework governing human behavior into the realm of its focus. Equipped with the wisdom of time in producing and reproducing thoughts, emotions, and behaviors related to crime, evolutionary perspectives provide a complementary approach to expanding the scope of explanation afforded to criminologists.

Evolutionary sociology; Evolutionary thinking in sociology; Relationship of evolutionary behavioral sciences and social sciences

Definition

Crisis in Sociology is the title of a book written by sociologists Joseph Lopreato and Timothy Crippen. It was published in 1999 and demands a stronger consideration of evolutionary thought in the discipline of sociology.

Introduction

In 1859 Charles Darwin laid the foundation of modern evolutionary disciplines and thereby changed the way we thought about the position of our own species and its history. About 100 years later, the works of Richard D. Alexander, Richard Dawkins, Robert Trivers, George C. Williams, Edward O. Wilson, and others began to change also the way we think about our social behavior and social evolution, which were the main subjects of traditional social sciences like sociology up to that time. At the latest when Wilson published his book *Sociobiology: The New Synthesis* in 1975, a more or less adversarial debate arose (a) among evolutionary biologists, (b) between sociologists and evolutionists, and (c) most relevant for this entry, within sociology itself. The rise of new evolutionary disciplines like *sociobiology* in the 1970s or *evolutionary psychology* in the 1990s and their explanatory power when it comes to human social behavior represented a challenge for areas of sociology and their representatives.

Crisis in Sociology was neither the first publication from within sociology that calls for evolutionary thinking in the discipline nor is it the last. However already the book's title makes it stand out a bit from other likewise important and profound publications. Its title perfectly reflects the state of sociology (as early evolutionary sociologists would say) in the advent of modern evolutionary disciplines like sociobiology or evolutionary psychology. Out of the many relevant sociological publications on this topic, a few (due to the limits of this brief entry) will be presented subsequently.

The Debate Within Sociology

In the first years following 1975, the debate within sociology began. Van den Berghe, for decades one of the most vehement advocates of an integration of evolutionary insights into sociology, published an evolutionary informed sociology textbook as early as 1975. More than 40 years ago, he already discussed topics still highly relevant in today's sociology, like human families, inequality, politics, economics, religion, etc. from an evolutionary point of view. But most sociologists seemed to be reluctant to see the bigger picture at those times, so Ellis (1977) felt the need to publish a hypothetical paper about the decline of sociology between the years 1975 and 2000. Arguably an early wakening call towards sociologists before their discipline will possibly be absorbed by sociobiology. Ellis (1977, pp. 60–61) also provided his readers a comprehensive outline of evidence for evolutionary influences on diverse forms of human social behavior from the past two decades, such as aggression, altruism, cooperation, pair bonding, care for offspring, etc.

Moving forward almost 20 years to the 1990s, the situation doesn't seem to have changed. While new evolutionary disciplines besides sociobiology have emerged, especially evolutionary psychology, the debate within sociology was still the same. Nielsen (1994) gave another introduction to sociobiology and a review of its findings for sociologists, and shortly afterwards Ellis (1996)

predicts a bleak outlook for sociology if the discipline continues to refuse the biological factor. Ellis (1996) attributed sociologists "biophobia" to four causes, namely, semantic factors, a lack of training in biology, an exclusive focus on humans, and moral or political factors (p. 24). Most notably, he provides an extensive amount of literature sources and an overview of work already done by (who we today may call) evolutionary sociologists within the past two decades (p. 26–27).

In 1999 Lopreato and Crippen published *Crisis in Sociology*. They claimed to be "proud but concerned sociologists" (p. xi). The book was written out of the deep concern that sociology may not be able any more to meet real-world problems and should finally participate in the evolutionary revolution or otherwise will lead itself to "academic self-destruction" (p. xi) and get cannibalized by more up-to-date disciplines. Lopreato and Crippen granted sociology some more 25 years (cf. Ellis 1977) before it "risks deletion from the academia" (1999, p. xii) in case it will not pick up on modern evolutionary behavioral science. A few years later, Freese et al. (2003) gave an introduction to current disciplines like evolutionary psychology and behavioral genetics for their sociological audience. Then Machalek and Martin (2004) recognized the emergence of *evolutionary sociology*. But even though three decades of debate within sociology had passed and evolutionary disciplines made great progress in those years, both papers still had to discuss and dismantle misconceptions or misbeliefs like genetic determinism, etc.

In 2006 Barkow edited a book about *Darwinism for Social Scientists* with chapters from major social scientists, psychologists, and anthropologists, among them Ullica Segerstrale, whose work on the sociobiology controversy got famous. In its introduction, Barkow (2006) recommends that social scientists finally "come to grips with Darwin" (p. 44). By using the metaphor "sometimes the bus does wait" (p. 3), he shows some optimism that it is not too late for social scientists to integrate evolutionary thought, admittedly not in an unreflecting manner but critically and seriously. Another decade passed, and

Horowitz et al. (2014) published their investigation of 155 sociological theorists' thoughts about evolutionary biology. Their survey data clearly revealed the picture of sociology as a still divided discipline. For example, 40% of respondents found evolutionary explanations of male violent crime implausible (Horowitz et al. 2014, p. 498). Even higher rates of attributed implausibility of evolutionary explanations were found for male pornography use (50%) or virginity (53%). On the other hand, the highest plausibility of evolutionary explanations among their respondents was found for the taste for fats or sugars (60%). As others before, Horowitz et al. (2014) concluded that sociologists' acceptance or refusal of evolutionary explanations is significantly due to political reasons and worldviews.

The Need for Darwin

Sociology has met several crises in its long history – political, theoretical, and methodological ones. Lopreato's and Crippen's (1999) book *Crisis in Sociology* attempts to solve the recent crisis by integrating evolutionary theory into sociological theorizing and research. Both authors at that time already had a long record of publications which pursued the same objective. Their 1999 book received mixed reviews in sociological journals. A very positive one came from Badcock (2000) who obviously appreciated Lopreato's and Crippen's approach of overcoming sociology's crisis by picking up on evolutionary thought. *Crisis in Sociology* is structured in three main parts, each of which is divided into three (part one), two (part two), and four (part three) chapters.

Part one gives an overview of sociology's history from the early classics to the crisis of modern sociology. As students of sociology learn in introductory courses, sociology itself emerged out of crises. Changes in society and economy in the eighteenth and nineteenth century (industrialization, urbanization, societal conflicts, political turmoil, etc.) required a discipline to

understand those new challenges and maybe help to solve some issues. Chapter ("The Early Promise") of the book deals with some of those classical scholars of sociology, among them Auguste Comte, Karl Marx, Émile Durkheim, and Max Weber. All of them were great theorists who analyzed societal phenomena at their time. As Lopreato and Crippen criticize, they are rarely fully read and understood today. In principle such sketchy treatment of sociological theories may be one reason for modern sociology's crises. Chapters ("The Deepening Crisis") and ("Why the Crisis: A Sketch") are discussing the crisis in sociology as well as their reasons. Although there were great theorists like Robert K. Merton or Talcott Parsons in the twentieth century, sociology in general suffers on the one hand from still assuming that human behavior is solely due to socialization and on the other hand increasingly from its fragmentation, it is postmodern orientation, its mediocrity, and from overstated political correctness. While some sociologists may call that intellectual diversity and regard it as an advantage, Lopreato and Crippen may not.

Part two of the book presents an introduction to evolutionary theory (Charles Darwin: Theory of Natural Selection) through discussing natural and sexual selection and then gives an overview of key concepts like kin selection, fitness, altruism, parental investment, as well as a brief portrayal of the sociobiology controversy and the later debate between sociobiologists and evolutionary psychologists. Part two is especially helpful, since the book is written for a sociological audience and provides the relevant information in an accessible way. Finally part three may be considered to be the core of *Crisis in Sociology*. In its four chapters, the authors familiarize their audience with thinking evolutionary about well-known and utterly relevant sociological topics. Chapter (Sex Differences in Same-Sex Aggression) deals with sex differences, mating strategies, family structures, parenting, division of labor between the sexes, etc. Sociologists should become aware that there are biological influences to male and female behaviors and

strategies. Of course not a single evolutionist would deny that always both, genetic and environmental influences, interact. Genetic determinism is not what evolutionary behavioral science is suggesting – but often sociologists wrongly assume exactly that.

Chapter (“Fundamentals of Social Stratification”) discusses social stratification (a topic relevant to sociology at all times in its history). Drawing on primate dominance orders and human sexual selection, Lopreato and Crippen try to broaden sociological thinking and understanding of this phenomenon which has indeed always existed despite numerous attempts to mitigate it. The last chapter 9 is entitled “The Clannish Brain” and illustrates how ethnic conflicts – or more generally speaking, in-group versus out-group conflicts – happen and persist. Understanding that our species lived in small groups for the longest time in its history and that kin selection and altruistic behavior as well as in-group favoritism were relevant aspects may lead to a deeper grasp of such conflicts in today’s globalized and anonymous society. Needless to say that insight is relevant for solving real-world problems – what sociology certainly strives for. It is true for the last four chapters that the authors almost always try to integrate sociological and evolutionary views on those topics.

When reading the book, one clearly gets the impression that Lopreato and Crippen were sociologists, are sociologists, and will remain sociologists. They neither aim to reduce sociology to biology nor do they intend any dissolution of their discipline by completely shifting to any of those new evolutionary sciences. The authors instead obviously want to enrich their own discipline with evolutionary theory and insights from those disciplines so that sociology will remain a relevant and up-to-date social science. From the first sentence to the last one, the book is written with hope, profundity, and eloquence. One will hardly find a lot of books covering sociological and evolutionary knowledge and insight in such profundity in one place.

Conclusion

What better conclusion to give than Badcock’s final statement in his review of *Crisis in Sociology*: “By any standards, this is an outstanding and timely book, superbly written, faultlessly argued and unsurpassably well-informed. Sociology will ignore it at its peril, but whether Lopreato and Crippen will be able to do anything to resolve the crisis remains to be seen. Failure, however, will not be their fault.” (Badcock 2000, p. 600).

Critical Period

Yan Wang and Jing Guo
Department of Psychology, Fudan University,
Shanghai, China

Synonyms

Crucial time; Sensitive period

Definition

A maturational stage during the lifespan of an organism in which the organism's nervous system is especially sensitive to certain environmental stimuli. The organism is more sensitive to environmental stimulation during a critical period than at other times during its life.

Introduction

The phenomenon of critical period was first described by William James (1899) as “the transitoriness of instincts.” The term “critical period” was proposed by the Austrian ecologist based on his observations that newly hatched poultries, such as chicks and geese, would follow the object, usually their mother, if exposed to within a certain short time after birth.

According to Lorenz, if the young animal was not exposed to the particular stimulus during the “critical period” to learn a given skill or trait, it would become extremely struggling to develop particular behavioral pattern in the later life.

A vast of existing literature has identified the existence of critical period in vision, hearing, and auditory processing. Quite a lot of early interventions have been carried out to provide more beneficial environmental stimuli for early children.

Critical Period and Language Development

The critical period hypothesis, as a long-standing debate in linguistics and language acquisition, briefly states that the ability to acquire language is biologically linked to chronological age. According to CPH, the first few years of life are the critical period for an individual to acquire language. If not being exposed to the language during the critical period, the individual will never master the language fluently, especially the grammatical knowledge.

The evidence for the CPH is still limited. The support stemmed largely from theoretical arguments and analogies to other critical periods in biology, such as vision and hearing development. The existing literature is controversial on the nature of critical period in both first and second language acquisition. Though some research (Friedmann and Rusou 2015) supported the existence of the critical period in language acquisition, other literature (Vanhove 2013) still disputed this viewpoint. In addition, the duration of the period also varies greatly in different literatures.

Based on three central assumptions, Hurford (1991) proposed an evolutionary model of language acquisition in order to provide evidence for the evolutionary functionality of the critical period. Hurford believed language acquisition was an adaptation, which had a survival value for humans and was favored by natural selection. He indicated that knowing a language correlated positively with an individual's reproductive advantage. Because the experiment revealed no evolutionary advantage of acquiring more than one language, Hurford proposed the critical period has been evolved simply as a result of the lack of selection pressure. Hurford's research supported the existence of the critical period in language acquisition and pointed out it would end around the puberty.

Life History Theory and Critical Period

Quite a lot of research indicates the first few years of life were a critical period for children's social

development. John Bowlby proposed from birth to 3 years constituted the sensitive period for the establishment of children's attachment style (Bowlby 1969) and the deprivation of maternal care in the first few years of life would produce irreversible harmful effects on individual's ability to establish close emotional bonds with others (Bowlby 1951).

Based on the Life History theory several studies demonstrated the first 5 years of life might be a sensitive period for the development of individual's life history strategies due to at this stage young child would be most vulnerable to the environmental influences. For example, one study (Simpson et al. 2012) proved exposure to environmental unpredictability during the first 5 years of life, but not a later stage from 6 to 16 years old, could predict individual's sexual and risky behaviors at age 23 most powerfully. Those experiencing more unpredictable, rapidly changing early environments tended to adopt a faster life history strategy at ages 23. Study (Belsky et al. 2012) also demonstrated that environmental unpredictability during the first 5 years of life could predict more sexual partners at age 15 than unpredictability occurring later in childhood or adolescence. Another recent longitudinal study (Doom et al. 2015) found exposure to early greater environmental unpredictability, such as changes in residence, cohabitation, and parental occupation, from 0 to 5 years independently predicted externalizing behaviors in both adolescence (directly) and early adulthood (indirectly).

In addition, Draper and Harpending (1982) pointed out father absence at the age from born to 5 years old could predict most powerfully male's aggression, competition, low paternal investment and derogation of females and femininity at adolescence, and predict female's fast reproductive strategies. They believed this stage constituted the critical period for receptivity to fathering. Consequently they stated the first 5 years of life could be regarded as a developmentally sensitive period for being shaped by the absence of father. Similarly (Ellis 2004) also stated that the critical period for girls' learning of reproductive strategies, such as the timing of

pubertal maturation and sexual behavior, would be the first 5 years of life.

As a result, researcher (Susman 2006) believed young children's neural systems during early sensitive periods could be influenced by the inconsistent and unpredictable environments. This kind of early experiences could shape and "prepare" individual's brain for dealing with the similar situations later in life (Ellis and Del Giudice 2014).

Conclusion

The existence of critical period has been extensively evidenced. Though being widely known the CRH is still facing much controversy in the existing literature. Based on Huford's evolutionary model of language acquisition it would be reasonable to explain the existence of critical period from an evolutionary psychology. In line with Life History theory the first 5 years of life constitutes the sensitive period for the development of life history strategies, during which young child is most vulnerable to the influence of environmental unpredictability. Female's reproductive strategies can be powerfully shaped by the father absence during the sensitive period of from birth to 5 years.

Critical Period of Acquisition

Niloufar Lueke and Adam Lueke
Ball State University, Muncie, IN, USA

Synonyms

Second language acquisition; Multilingualism

Definition

A developmental time interval that is optimal for experience-induced neural plasticity; with respect to bilingualism, this refers to a window of time during which the neural representation of the language system is malleable to second language acquisition, similar to first language acquisition.

Introduction

We begin life with biological systems that support the ability to acquire human language. Speech perception and ultimately the acquisition of language has been shown to be influenced by multiple critical periods (CPs) that open and close at different time points during development (Werker and Hensch 2015). The discussion of the CP of acquisition, as it relates to bilingualism, entails defining what is meant by “acquisition,” as well as what is meant by a “critical period.” This entry will discuss bilingualism within the context of the CP model, and how this phenomenon can be understood from an evolutionary perspective.

Acquisition Versus Learning

Krashen (1982) made a distinction between *acquisition* and *learning*, thereby distinguishing two distinct modes of developing competence in a second language. The first way is language *acquisition*, which refers to a subconscious process whereby one is not consciously aware of the rules of the language they have acquired, but instead having a “feel” for correctness (e.g., grammatical sentences “sound” right, or “feel” right, and likewise, errors feel wrong, even if the rule violated is unknown). This is similar to the way children acquire their first language and can be thought of as implicit or procedural learning. The second way to develop competence in a second language is via language *learning* or conscious knowledge of a second language (e.g., knowing the rules and being aware of them). In this case language-based knowledge is integrated into an existing system, through conscious purposeful

endeavor with persistent efforts (e.g., memorization, active participation). This second mode can be thought of as “knowing about” a language with respect to its grammar or rules and is equivalent to explicit or declarative learning. This entry will apply Krashen’s acquisition-learning distinction when discussing the CPs of bilingual acquisition, which in turn points to the implicit or procedural acquiring of language during infancy, which is automatic and effortless. When discussing CP of bilingual acquisition, this entry will rely on the distinction between implicit and explicit knowledge of language, as acquisition of semantic knowledge, which is declarative knowledge rather than procedural/implicit, remains less stringently bound to the effects of CPs.

Definition of Critical Periods

The conceptual definition of a CP refers to a window of time, typically in early development, during which neural representation of a particular system is open to experience-induced plasticity. This is considered an optimal time for rewiring of neural circuitry on the basis of input from the environment via sensory experience. While environmental influences can have an impact on a particular system at time points outside of the CP, the impact will not be as profound, as the system may be more resistant to reorganization outside of this “critical” or “sensitive” period. CP can therefore be thought of a period of time during which experience, or lack thereof, can induce significant changes in wiring. Biological mechanisms of CPs involve molecular triggers which shift a neural circuit from an immature to plastic state, thereby initiating or opening the CP; likewise, there are molecular brakes on plasticity that initiate the consolidation of the neural circuit from a plastic to stable state, thereby closing the CP. However, these critical windows may not close completely, and can reopen via targeted genetic, pharmacological, or behavioral manipulations, thereby reinstating plasticity later in life and enabling learning throughout the life span. For a review of the specific processes that open CPs, mediate their operation, and close

(or reopen) them refer to Werker and Hensch (2015).

Critical Period of Bilingual Acquisition

The CPs of language acquisition can be interpreted as windows of time that support perceptual narrowing of the speech sounds of infants’ native language(s). *Perceptual narrowing* refers to a developmental process that improves perception for socially relevant information of native stimuli experienced in the environment over foreign or nonnative ones (e.g., Lewkowicz and Ghazanfar 2009). Enhanced sensitivity to frequently encountered and meaningful environmental input is achieved by strengthening the neural representations that underlie such perceptual discrimination (e.g., Werker and Tees 1984). Through this process, an infant’s perceptual abilities become specialized for aspects of their social environment that has adaptive significance, helping them become more adept members of their community. Perceptual narrowing for native compared to foreign stimuli occurs across a number of socially relevant domains (e.g., faces, voices, music, etc.), including language and its various aspects (e.g., vowel and consonant contrasts, tone languages, visual language, and sign language).

The languages of the world have different collection of speech sounds that are used to form words and contrast meaning. For instance, many native Japanese speakers have difficulty with perceiving and producing English /r/ and /l/ in words such as “rate” versus “late.” This contrast is challenging for many Japanese speakers, especially those who began learning English later in life, because unlike English, Japanese groups phonetic units /r/ and /l/ into the same phonetic category (Japanese/r/), thereby treating any acoustic difference between the units as irrelevant (for a review, see White et al. 2013). While adults have difficulty discriminating some speech sounds that are not used in their native language, studies have shown that young infants, up to a certain age, can perceive and discriminate many native and nonnative phonetic contrasts, even without prior listening experience (e.g., Werker and Tees 1984).

Infants' first year of life is marked by CPs that support perceptual narrowing of various aspects of language that shift their phonetic perception from language-universal to language-specific by maintaining sensitivity only to native contrasts, as perception of nonnative contrasts declines (e.g., Werker and Tees 1984). While the CP of some aspects of language (e.g., vocabulary learning) remain open across the lifespan, the degree and timing of neuroplasticity for phonology and syntax are thought to be highly sensitive to the age at which language input occurs (e.g., Werker and Tees 2005). For instance, while English-speaking adults have difficulty discriminating two different "d" sounds that are used to contrast meaning in Hindi but not in English; however, 6–8-month-old monolingual English infants were as proficient as adult native Hindi-speakers at discriminating these Hindi (nonnative) phonemic contrasts. In contrast, 10–12-month-old monolingual English infants no longer succeed in differentiating this contrast, whereas Hindi-learning infants maintain sensitivity (Werker and Tees 1984). Previous studies have shown that perceptual narrowing for consonant discrimination is seen between 8 and 10 months of age, whereby infants reliably discriminate both native and nonnative speech sound differences by 8 months of age, but by 10–12 months of age they have difficulty discriminating acoustically similar nonnative contrasts (for a review, see Maurer and Werker 2014). Likewise, narrowing effects have been shown for vowel discrimination, for discrimination of lexical tone, and for discrimination of hand signs that are used in sign languages (for recent reviews, see Werker and Hensch 2015; White et al. 2013). Thus, while the nervous system maintains discrimination sensitivity, even for nonnative and never-before-heard speech sounds until 10–12 months, it is after this period that marks the beginning of consolidation period and a gradual decline in plasticity.

Up to 10 months of age, infant perception of speech sounds is fairly plastic and easily changed by means of minor exposure; however, after this window of time, double the exposure is necessary to bring about the same amount of change – this may be indicative of solidification of native sound

categories and a gradual decline in plasticity (for a review, see Werker and Hensch 2015). After this time point, successful learning of a second language has been generally agreed to be highly sensitive to the age at which second language learning begins, such that late compared with early learning of a second language is associated with lower proficiency, even though some individuals may achieve native-like proficiency (White et al. 2013). The wide variation observed in second language proficiency in adult learners has been attributed to attainment not being limited to age of second language acquisition, as other individual difference factors (e.g., working memory, intelligence, aptitude, developmental disorders, affective states, and memory systems, as well as auditory perceptual, neurophysiological, neuroanatomical, potential genetic factors, and noncognitive and nonlinguistic factors, such as motivation and sociocultural factors) play a part in second language development after the closing of a CP (for a review, see Morgan-Short et al. 2014).

Conclusion

The abovementioned perceptual narrowing of socially meaningful environmental input by 12 months of age appears to shape linguistic abilities by catalyzing a shift in phonetic perception from language-universal to language-specific (i.e., a shift from multi- or bilingual acquisition to a monolingual one). This developmental process goes hand in hand with a decline in discriminating other nonnative and therefore socially irrelevant information (e.g., other-race faces; for a review, see Friendly et al. 2013). From an evolutionary perspective, fast and easy identification of group and species members, supported by perceptual narrowing, may have conferred safety and survival benefits, as it enables one to easily discern in-group versus out-group members in order to help inform decisions such as whether to approach or withdraw from a situation. Thus, the ability to prioritize the processing of socially relevant environmental input may have facilitated the development of

becoming a fully functioning member of one's group.

While perceptual narrowing of nonnative speech sounds, or CP of second language acquisition, appears to be largely accomplished by 10–12 months post-birth, the human brain remains highly capable of plasticity beyond this age. However, reinstating sensitivity to a nonnative speech sound (e.g., learning a second language) and initiating plasticity, or reopening a CP beyond its initial closure, requires additional factors such as conscious learning and effort. This is in contrast to the effortless first language acquisition observed in children, which is an astonishingly rapid process. This may allude that the age-sensitive cognitive process of acquiring another language, post-CP, may have not been selected for propagation. The reasons for why acquiring a second language may not have been selected for can also be understood in the context of our ancestors interactions with their environment.

Evidence from the environment of our nomadic ancestors suggest that while mastering a language early in life was a highly useful evolutionary adaptation, acquiring a second language later in life may have not been as adaptive or advantageous, and consequently not selected for (Hagen 2008). As Hagen (2008) describes, this evolutionary assumption is based on the environmental circumstance of our nomadic, hunting-and-gathering human ancestors, who represent the vast majority of our past. When anatomically modern *Homo sapiens* began migrating from Africa into the Eurasian continent around 120,000 BCE, their diaspora was exceedingly sparse, compared to modern standards, and populations that averaged about 150 members (considered an ideal approximate group number in order to maintain group manageability) splintered when groups became too large. Splintering over time led to loss of contact with the former group, prompting language drift, and eventually new languages – a path that ultimately gave birth to the diverse languages that evolved across the African, Eurasian, and later the American continents (Hagen 2008). Moreover, several population bottlenecks in our past and subsequent

dramatic drops in our populations, in addition to a nomadic lifestyle, may have contributed to lack of sustained intergroup contacts among our nomadic ancestors. Given that the life expectancy of our ancestors was about 35 years, and considering that a child requires 3–4 years of exposure to a language to reach fluency, it is difficult to imagine circumstances in which all adult members of various nomadic groups to have had access to 3–4 years of steady exposure to a second language in adulthood. The transition from a nomadic to an agricultural lifestyle may have enabled intercultural contacts; however, these contacts would have been brief at most, and may have been marked by competition and aggression, as early human groups had to compete with other groups for scarce resources. It may have been therefore required less effort to ward off intruders or conquer enemies, than it does to expend effort to learn to communicate with them by acquiring a second language in order to negotiate and reach agreements with intergroup members. Considering the very recent globally interconnected and multicultural development in our history, and longer lifespan, our species may be progressing toward another evolutionary adaptation that may favor bi- or multilingualism.

Crocodilian Bait Hunting

Vladimir Dinets

University of Tennessee, Knoxville, TN, USA

Synonyms

Crocodilians using hunting tools; Crocodilians using lures

Definition

Crocodilian bait hunting refers to crocodilians (crocodiles and alligators) using various lures to attract their prey.

Introduction

Use of objects as hunting lures is very rare among animals. Until recently it has been known only in captive capuchin monkeys, a few bird species, and one insect (Shumaker et al. 2011). There were a few observations of saltwater crocodiles (*Crocodylus porosus*) using fish prey leftovers as bait for birds (Shumaker et al. 2011) and of Orinoco crocodile (*C. intermedius*) using prey leftovers as bait for vultures (Dinets 2013), but in these cases it was unclear if baiting was intentional or accidental.

Dinets et al. (2013) found that at least two species of crocodilians use small sticks to attract and catch birds.

Mugger crocodiles (*C. palustris*) in India and American alligators (*Alligator mississippiensis*) in Florida were observed floating with sticks positioned across their snouts in pools where large numbers of egrets and other wading birds nested in trees (Fig. 1). Egrets that tried to pick up the sticks were caught and eaten.

Further observations in Louisiana found that alligators displayed this behavior predominantly

Crocodilian Bait Hunting, Fig. 1 A well-camouflaged mugger crocodile uses sticks on its snout to attract a bird looking for nesting material

in the vicinity of egret colonies and did so almost exclusively at the time of year when the egrets were building their nests and were actively looking for building material.

So far, this discovery is the only known case of reptiles using tools. It is unknown what stimulates stick-displaying behavior at particular locations and at particular times of year. The crocodilians might be reacting to large numbers of wading birds flying low over water, to the sounds made by courting birds, or to some other environmental clue. It is also unknown whether this hunting technique is an innate ability or a skill learned by observation. Hunting with sticks as lures by American alligators was probably more effective in the past, before the plume-hunting era of 1870–1910, when the numbers of wading birds in their range were much higher than today and huge egret colonies stretched for many miles (McIver 2003).

Conclusion

Using tools is just one of many complex behaviors recently discovered in crocodilians. Historically viewed as lethargic and dumb, crocodilians are now known to exhibit flexible multimodal signaling, advanced parental care, and highly coordinated group hunting tactics (Doody et al. 2013), as well as in various kinds of play behavior (Dinets 2015). These discoveries are interesting not just because they show how easy it is to underestimate the intelligence of even relatively familiar animals but also because crocodilians are a sister taxon of dinosaurs and flying reptiles; the behavioral complexity found in birds and crocodilians suggests that the behavior of non-avian dinosaurs and pterosaurs was most likely very complex as well (Dinets et al. 2013).

Definition

Cross-cultural expression generally refers to differences in the expression of traits and behaviors across cultures.

Introduction

Humans share many universals. However, culture plays an important role in influencing the way that behaviors and traits are expressed. There are many different cultures across the world. Is an experience for a person growing up in Central London the same as a person living in the slums of India, or the metropolis of Japan, or in a tribe in Africa? Clearly not. Individuals appear to shape and be shaped by their culture, thus influencing

psychological tendencies and behaviors. Therefore, what is applicable to one culture may not necessarily apply to another culture. Within this chapter, firstly I will provide a working definition of culture and will then highlight key evolutionary theoretical stances in the development and maintenance of culture, focusing largely on cultural variation. The latter section of this chapter will discuss the influence that cultural differences have on behavior and expressions, with examples of empirical research.

What Is Culture?

Culture is not easily defined. The single term “culture” encompasses a broad range of aspects. A widely accepted and inclusive definition of “culture” is the “sets of practices, beliefs, ideas, values, inventions, artifacts, and attitudes that characterise groups of people” (Gangestad et al. 2006, p. 78). Across the globe, people differ in their practices and heritage. Culture extends beyond food, crafts, and geography; it revolves around the central beliefs, behaviors, and the identity of a group. There are many indigenous cultural expressions, which can take the form of knowledge, practices, stories, rituals, music, art, and much more. Furthermore, mating behavior and parental styles differ cross-culturally. Therefore, culture has a pervasive influence on human behavior. Yet, despite the importance of culture to numerous disciplines, including psychologists, anthropologists, and biologists, it remains an underexplored and controversial research area.

Nonhuman and Human Culture

Cultural expressions and learning are apparent in both human and nonhuman species. However, they vary in complexity. Chimpanzees have excellent toolmaking skills; knowledge is passed between chimpanzees within groups. Some research has found, for example, that new methods (e.g. fo ant-fishing) can transfer from one chimpanzee community to another. However, there are many differences between humans and

primates, such as the capacity for imitation and language ability. These capacities in chimpanzees can be likened to “culture” in humans. When we consider human populations, the picture is much more complex. Some behavioral traits can be apparent in some cultures, but not others, like riding a bike. Alternatively, other cultural aspects merely differ in expression; one of the clearest examples of this is language. People in different cultures all possess language, yet the content and qualitative aspects differ.

Evidently, in both human and nonhuman species, culture is important. One main question that follows then is, how are these culture-specific expressions and behaviors integrated and maintained?

How Does Culture Develop?

This is no unified explanation for how culture develops. The cultural evolution approach applies Darwinian evolutionary theory to culture. Specifically, the transmission of culture has been analogized with transmission at a genetic level. In other words, human cultural expressions (e.g., knowledge, customs, languages) evolve and typically increase in complexity over time. Transmission and evocation are two proposed pathways that bring about cultural variation (Gangestad et al. 2006).

One proposed mechanism, by which cultural expressions are thought to be passed on between individuals and generations, is social learning and modeling/imitation (Henrich and McElreath 2007). Indeed, we frequently observe and learn from others. This method may be best exemplified which considering technological knowledge in cultures. For instance, individuals may impart agricultural knowledge onto other individuals which is passed on through generations and does not require individual learning. This is a form of cumulative cultural evolution (CCE) where beneficial traits are retained in populations, also labeled as a “ratchet effect” (Tomasello et al. 1993).

A second hypothesized process which may lead to specific cultural attributes being

passed on and maintained within cultures is the social and ecological conditions of a population, so-called evoked culture (Tooby and Cosmides 1992). For example, conditions of drought versus a plentiful source of water are likely to lead to different behavioral strategies within cultures. Following on from this idea, gene-culture coevolution theory (Richerson et al. 2010) posits a relationship between genes and culture. Specifically, culture frequently creates novel environments, which then apply selection pressures on genes. Put more simply, culture exerts an important influence on creating our human nature.

It is important to note that proposed social learning and environmental explanations are not mutually exclusive – it may be that both methods shape cultural expression. The next two subsections will provide examples of cross-cultural universals and differences.

Cross-Cultural Similarities

One of the most well-known examples that has created great debate over human universals across cultures is facial emotional expression. Early work by Charles Darwin suggested that judgments of emotional expressions are universal in humans. Following on from Darwin’s exploration, one of the most cited examples is the work by Paul Ekman and colleagues (e.g., Ekman and Friesen 1971), which typically highlighted universality in emotional expressions and recognition. This work found that six basic emotion categories (anger, disgust, fear, happiness, sadness, and surprise) were consistent across cultures – especially happiness and sadness. This ability to recognize emotional expressions was also found in illiterate tribes – hunter-gatherers in New Guinea and the Dani people of West Irian – with little or no previous interactions with outsiders. Hence, despite the diverse and rich cultures that we live in, emotional expression and recognition appear to be similar cross-culturally. However, not all studies support the universality of emotion (e.g., Crivelli et al. 2016). This highlights tentative conclusions when considering cross-cultural similarities in emotion perception.

Cross-Cultural Differences

Research has generally focused on investigating the similarities between groups. While this has been a fruitful exploration, it omits consideration of the diversity that cultures display. Indeed, there are evident and widespread differences in psychological realms across cultures, including attractiveness preferences. From an evolutionary stance, “true” universality is rare and often condition-dependent. Parasite threat and sex ratio, for example, create constraints that can in turn influence cultural behaviors.

An example that provides evidence for important differences across cultures is facial physical attractiveness preferences and parasite threat. Evidently, in some human cultures especially hunter-gatherer societies, pathogens can pose a risk to health. It is therefore advantageous for women to be attuned to signals of health and overall condition in potential mates. Indicators of poor health (i.e., open sores, yellow eyes) should be unfavorable when selecting partners, while high levels of physical attractiveness should be preferable as attractiveness is considered to be a marker of good health and parasite resistance (Symons 1979). Correlational analyses of cross-cultural data (Buss 1989) highlight that higher parasite occurrence is positively related to a preference for more physically attractive faces. Therefore, when considering facial preferences alongside culture, important differences occur. These differences are thought to arise from ecological and environmental factors. Unlike the example of facial expressions above, cross-cultural differences are apparent and appear contingent on cultural environment. Therefore, there are both similarities and differences in cross-cultural expressions and behaviors.

Conclusion

Culture is an integral part of human life. Although culture has been studied by many disciplines, most explorations are limited – focusing mainly on cultural similarities. Many debates still

surround culture, especially how culture develops and is then maintained across generations. Two methods of cultural transmission, proposed by evolutionary psychologists, are observation and environmental influences. Furthermore, the provided examples highlight important cultural universals as well as dissimilarities when judging expressions and attributes in faces. Overall, there appears to be great cultural and psychological variation amidst human universals. Going forward, culture remains a relatively new, contentious, and underexplored area. Thus, more explorations are required into how and why cultural variation exists while overcoming some key methodological challenges associated with exploring culture.

Cross-Cultural Pattern

Mariko Hasegawa
The Graduate University for the Advanced
Studies, Hayama, Japan

Synonyms

Cultural homicide patterns; Global homicide trends

Definitions

Extensive variability exists cross-culturally in the rates of homicide, however relatively invariant across cultures is the tendency for homicide rates to be predicted by inequality and to be primarily a male affair that peaks among men in their early twenties.

Introduction

Societies differ in their economic and political bases, and different cultures have different moral standards. Therefore, features of homicide such as rate of homicide per million individuals or apparent motives of the most frequent homicides differ greatly between societies in different cultures. However, there are several characteristics of homicide observed commonly across cultures, which can be explained from an evolutionary perspective.

Cross-Cultural Patterns in Homicide

Homicide rates per million individuals are extremely variable across countries and societies, as well as across time, for an individual society. Despite this variability, there is a strong trend toward the reduction of violence over the evolutionary history of humans. Evidence suggests that premodern, small-scale traditional societies may have had a higher homicide rate per 100,000 individuals than the worst homicide rates from modern societies (Kealy 1997; Pinker 2012). This trend toward greater non-violence may imply that the legal system in modern nation states have been effective in controlling for violence among individuals (Pinker 2012).

The homicide rates for modern, developed societies are determined by a complex mixture of social, cultural, and economic factors. Despite this, there are several culturally invariant patterns that can be detected in homicide patterns and predictors. First, a strong predictive factor of homicide is the degree of economic inequality among members of a society. This inequality, as measured by the Gini index, displays a very clear correlation with the homicide rate for many countries, states, and the same country through time (Daly et al. 2001; Hiraiwa-Hasegawa 2004). In all of the cases, the smaller the Gini index (i.e., the more equality across individuals in a region), the lower the homicide rate.

Another cross-cultural pattern that emerges is the tendency for homicides to be primarily perpetrated by men against men. Globally, the UN Office on Drugs and Crime (2013) reports that 80–97% of homicide perpetrators are men and 95% of the victims of homicide are men.

In addition to this, another, near universal pattern in homicide rate is its association with age, in which the rates of homicide by men rise sharply after puberty to a peak in the early 20s and then decrease afterwards (Daly and Wilson 1988). A study from Japan is interesting in this regard because no such age-related curve for homicide rate was observed cross-sectionally after the 1980s (Hiraiwa-Hasegawa 2004). Social and economic conditions for young men dramatically

changed after the Second World War in Japan. As the proportion of young men with higher education increased and Gini index decreased, the rate of homicide among young men gradually dropped. And when their rate of homicide was compared with those of older age categories, older men's homicide rates were higher than that of younger ones. However, when the age-specific homicide rates were calculated within each cohort, it revealed the age-homicide pattern described above, that is, the homicide rate was highest when men were in their early 20s and declined afterward.

Motivations for homicide across cultures also share some commonalities. For example, the motivations for male-on-male homicide is often based on competition for resources, status, and prestige, whereas the motivations for male-on-female homicide is often a response to sexual jealousy (Daly and Wilson 1988; Hiraiwa-Hasegawa 2004). Women commit homicide relatively rarely, but when they do, it is quite often the killing of their own baby, i.e., infanticide. In those cases, a mother kills their own newborn baby when she thinks that the baby's prospect of survival is very low, either because of the low physical fitness or no social support to rear the baby (Daly and Wilson 1988).

Conclusion

Homicide rates per million individuals are extremely variable across societies, but the global tendency is toward the reduction of violence. Although many factors are involved to determine homicide rate in a society, a strong predictive factor of homicide is the degree of economic inequality among members of the society: the smaller the inequality, the lower the homicide rate. In most societies, men are more often both the perpetrators and victims of homicide, and there is a strong age effect with a peak homicide rate in the early 20s. The motives for male-on-male homicide are often based on competition for various types of resources. Those patterns can be understood within the theoretical framework of sexual selection.

Cross-Cultural Punishment

Quésia F. Cataldo¹ and Sophia Lóren de Holanda Sousa²

¹Department of Psychology, Universidade Federal do Ceará, Fortaleza, CE, Brazil

²Department of Psychology, Universidade Federal do Ceará, Fortaleza, Brazil

Synonyms

Altruistic punishment; Castigation; Retribution

Definition

Punishment mechanisms are crucial to understanding the processes of cooperation in groups and can be found in different societies; the level of punishment varies according to environmental, social, and cultural factors.

Introduction

Cross-cultural studies defend the idea that punitive sentiment may be universal among humans (Price 2005). Punishment is understood as a central element for explaining the phenomenon of group cooperation (Kurzban et al. 2007). For example, models of the evolution of costly punishment suggest that societies in which this type of punishment is common will have stronger norms of justice and prosociality because this punishment allows the development of stable rules to deter invading deserters (Henrich et al. 2006). Regarding moral punishment, it plays an important role in regulating an established moral system in which those who punish seek to identify and punish those who behave immorally (Hofmann et al. 2018).

Thus, it is important to discuss how punishment, so crucial to the understanding of cooperation processes, is identified in other societies. As Petterson and Vasey (2016) point out, cross-cultural studies depart from the principle of examining human behavior in various cultural contexts so that behavioral differences and similarities are elucidated.

Cross-Cultural Studies on Punishment

A study conducted by Henrich et al. (2006) in different continents (Africa, North America, South America, Asia, and Oceania) in different environments (e.g. urban, mountainous tropical forest, Savannah-woodlands), assessed second-party punishment through costly punishment and identified that costly punishment has a universal standard, despite differences in the level of

punishment among populations. In this study, some societies exhibited a high disposition for punishment, such as Tsimane, the Shuar, Yasawa, and the Samburu, sedentary and semi-nomadic societies whose basic economy is horticulture. However, most societies studied, which include societies living in urban, sedentary, wage-labor environments (e.g., Accra city, Missouri, and Dolgan/Nganasan), have shown a tendency to punish less.

In this sense, people from different cultures can give different attributions to the same situation because their beliefs are influenced by culture. Studies suggest that the intensity and form of control varies between Chinese and American culture, for example, with the Chinese being characterized by more punitive aspects. In China, the punishment or threat of it has a function of control over the behavior of individuals, so that they obey social norms; while in Western cultures, punishment functions as a means of justice for certain acts (Friedman et al. 2005).

Regarding religion, the belief in gods with moralistic and punitive characteristics, who may play a chastising role against those who do not cooperate with the social order, is characterized as a factor that explains human cooperation. These patterns can be explained from an evolutionary point of view, since with cultural evolution it is possible to establish patterns of self-reinforcing beliefs and practices, which remain because they are possibly associated with punishment (Purzycki et al. 2016).

Conclusion

Although it is an incipient area, cross-cultural studies can provide data on the universality of some behaviors and traits, facilitating the understanding of the factors that selected and maintained them. Regarding punishment, it is observed that its application is fundamental for the development of cooperation, but it should be emphasized that the level of punishment changes according to environmental, social, and cultural factors.

Cross-Cultural Research on Grandparental Investment

Xiuyun Lin and Yongqiang Jiang
Institute of Developmental Psychology, Faculty of Psychology, Beijing Normal University, Beijing, China

Synonyms

[Grandparental involvement](#); [Grandparenting](#)

Definition

Grandparental investment refers to the various types of tangible or intangible resources (like time, energy, material, and solicitude) that grandparents, including maternal grandmother, maternal grandfather, paternal grandmother, and paternal grandfather, provide for grandchildren.

Introduction

In contemporary societies, increases in life expectancy and grandchild survival have enhanced the opportunities for grandparents to invest on their grandchildren (Coall and Hertwig 2010). The percent around the world is high. For example, in the USA two decades ago, more than half (60%) of grandparents provided occasional or more frequent grandchild care (Fuller-Thomson and Minkler 2001). Today in China, about three quarters of the children under age of 6 years old are routinely cared by their grandparents (Yue 2018). However, the investments or cares from different grandparent types (i.e., maternal grandfather, maternal grandmother, paternal grandfather, and paternal grandmother) are not equal but discriminative.

Evolutionary Perspectives

In explaining the discriminability in grandparental investment, evolutionary perspectives have provided considerable literatures. Kin selection theory (Hamilton 1964) is commonly acceptable. Investment from grandparents on their biological grandchildren can be seen as effective indirect strategy, as the results of genetic relatedness, to increase their inclusive fitness. The theoretical genetic relatedness between any grandparent type and grandchild is the same ($r = 0.25$ on average). As such, the average levels of investment from any grandparent type might be similar. However, human males have potential uncertainty in their biological relationship to their children (i.e., paternity certainty hypothesis; Euler and Weitzel 1996). The uncertain links of paternity

between grandparents and grandchildren render the ordered level of investment: maternal grandmother > maternal grandfather or paternal grandmother > paternal grandfather. Sex-specific reproductive strategies (Euler and Weitzel 1996) further the predicted rank order. In mammals, the production of eggs and the internal gestation render that females expend maximal resources on parental effort, whereas males reserve resources for further mating effort. Consequently, maternal grandparents ought to invest more in their daughters and daughters' children than paternal grandparents invest in their sons and sons' children. The combined effect of paternity uncertainty and sex-specific reproductive strategies thus predicts the clear rank order: maternal grandmother > maternal grandfather > paternal grandmother > paternal grandfather, representing as matrilineal biased (Coall and Hertwig 2010).

The abovementioned order is not supported by other hypotheses. The grandmother hypothesis proposes that menopause and the lengthened post-menopausal lifespan provide the evolutionary importance of grandmaternal investment (Alvarez 2000), while grandfathers are presumed to be more engaged in mating effort than nepotistic investment in grandchildren, leading to the order as maternal grandmother or paternal grandmother > maternal grandfather or paternal grandfather. The Trivers-Willard hypothesis (Trivers and Willard 1973) proposes that by providing investment to grandchildren, grandparents could facilitate their children's fertility; hence, the reproductive potential of the children plays a role in biased grandparental investment. In addition, the asymmetric genetic relatedness hypothesis (Chrastil et al. 2006) emphasizes that the genetic relatedness between grandparents and grandchildren is symmetric on autosomal genes but asymmetric on sex chromosomes. Granddaughters and grandsons have 50% chance of inheriting an X chromosome from maternal grandmother or grandfather. Granddaughters definitely do not obtain one X chromosome from paternal grandfather, whereas grandsons definitely inherit Y chromosome from paternal grandfather. Thus, paternal grandparents provide investment for granddaughters and grandsons more discriminatively than maternal grandparents.

However, the evolutionary perspectives are, to some degree, difficult to provide some specific and proximal explanations for biased grandparental investment in different cultures or societies (Coall and Hertwig 2010). In some WEIRD (Western, Educated, Industrialized, Rich, and Democratic; Henrich et al. 2010) societies, including the USA, Europe, and Australia, the biased pattern (maternal grandmother > maternal grandfather > paternal grandmother > paternal grandfather) has often been supported. For example, in the Netherlands, it was found that grandparental investment biased toward daughters' children (Kaptijn et al. 2013). However, in non-WEIRD samples, research has been relatively limited. Although that, limited studies have demonstrated that in traditional Western rural societies, it often showed high levels of patrilineal biased grandparental investment. For example, in rural Greece, paternal grandparents were found as the primary caregivers (Daly and Perry 2019). Besides, in Asian cultures, like China, the traditional patriarchal nature of filial piety prioritizes paternal above maternal relations, leading to more patrilineal than matrilineal biased grandparental investment (e.g., Chen et al. 2011). Therefore, the biased grandparental investment is more rooted in variations of specific sociostructural ways.

Cross-Cultural Research

Unlike the evolutionary perspectives, cross-cultural approach focuses on how different cultural values, like patrilineal or not, the norms of grandparental involvement, reciprocity, family obligations, and responsibility, shape the biased grandparental investment. The most salient cross-cultural difference is about patrilineal or not. Most published literature on grandparental investment relies on WEIRD samples (e.g., Danielsbacka and Tanskanen 2012; Danielsbacka et al. 2011). In these WEIRD societies, it doesn't favor patrilineal culture but mother-daughter bonds. And, paternity uncertainty is relatively higher than that in patrilineal societies; so, the matrilineal pattern of biased grandparental investment is often found (e.g., Bishop et al. 2009). However, in patrilineal

societies, it often shows high levels of paternal grandparental investment (Strassmann and Garrard 2011). China is a typical patrilineal country and often included as the object of cross-cultural research with Western ones (e.g., Burnette et al. 2013; Kaptijn et al. 2013). In China, the intergenerational transfers or ties are rigidly patriarchal. Historically, patrilocal extended family has been the dominant family form in East Asian and Southeast Asian countries, with adult sons (at least one of the sons), daughters-in-law, and descendants living in the same house (Mehta and Thang 2011). Parental preferring to invest toward sons than daughters lies in the patrilineal kinship system. For example, Wang and Chen (2019) asked a sample of childless female undergraduates to imagine being a grandmother and to report their biased investment on hypothetical grandchildren. The results revealed the strong preference to invest toward sons' children than daughters' children. Using the China Health and Nutrition Survey, Chen et al. (2011) reported that co-residence with paternal grandparents (high levels of grandparental investment) was about three times than with maternal grandparents on average (35% vs. 10%). Again, in Goh and Kuczynski's (2010) research, they reported a survey conducted in 2006 and that among 1301 grandparents from 738 households in Xiamen, 40% were paternal grandmothers, followed by maternal grandmothers (31%), paternal grandfathers (18%), and maternal grandfathers (17%).

The cross-cultural differential may be also from the heterogeneity among grandparents and ambiguity of the norms related to grandparenthood. Some anthropological researchers treated grandparental survival and senescence as the indicators of grandparental investment (Strassmann and Garrard 2011). In the psychology-related division, the roles of grandparents range from "uninvolved" to "occasional helper" or "long-term helper" or "long-term surrogate parent" or "custodial grandparent" in different studies. These different roles per se may reflect the different levels of grandparental investment. More importantly, the differential is usually covered by cultural differential. In WEIRD societies, state

welfare provisions substitute for some kin support in raising children. Investment for grandchildren is viewed as an option. The common norm of grandparental investment is "being there" but "not interfering" (Mason et al. 2007). That is, grandparental investment tends to be occasional and the level is relatively low. By the contrast, Black and Hispanic grandmothers tend to play a considerable role in caring grandchildren. The pattern does not only reflect varied cultural norms but also is the responses to socioeconomic disadvantage or parental difficulties (e.g., incarceration and mental illness) (Hayslip et al. 2019). In Asian families, grandparental investment is viewed as familial duty or obligation (Mehta and Thang, 2011) and the level is also very high (e.g., Chen et al., 2011). On the one hand, households rather than individuals or couples ought to overcome familial difficulties. Grandparents, especially grandmothers, are the optimal alloparents because of their low costs but enough time, energy, creditability, and experiences in childcare. Essentially, it is a family adaptive strategy, maximizing the well-being of the whole family. On the other hand, the elder generation holds a sense of "responsibility-oriented ethics." They fulfill their responsibilities and obligations toward their children and grandchildren. Accordingly, the Chinese context of grandparental investment is structural and functional, in which grandparents can provide matched or more caring and instructions for grandchildren than their adult children. For example, for some Chinese rural left-behind children, intergenerational investment is commonly from paternal grandparents; the grandparents are significant agents as same as their parents. In other Asian countries (e.g., South Korea, Vietnam, or Myanmar), the cultural norm is similar (Mehta and Thang, 2011), although the extent of grandparental investment may be discrepant (e.g., Knodel and Nguyen, 2015; Ko and Hank, 2014).

However, with the development of societies and integration of Eastern and Western cultures, the cross-cultural differential between patrilineal and matrilineal patterns of biased grandparental investment seems being weakening in some Asian societies, like China. In a recent survey conducted

in six cities of China, it was found that the proportions of maternal grandparents and paternal grandparents involving grandchild care were similar (49.5% vs. 50.5%), although grandmothers were always more than grandfathers (Yue, 2018). Decrease in fertility rate may be a predominant factor. In China, it was specifically driven by the One-Child policy. From 1978, Chinese government implemented the One-Child policy. The one-child generation started families from about 2000 and had a new generation of one-child. Although the policy was abolished from 1st January 2016, the national fertility rate is still at low level. In many families, it shows a “4-2-1” intergenerational pattern, i.e., four grandparents, two parents, and one child. Four grandparents had only a grandchild. The artificially controlled fertility may substantially confound the biased grandparental investment. And, with the development of urbanization, the average household size declines. The shift toward the nuclear family structure would result in the decline of grandparents’ co-residence. Statistics from the 2010 Census in China illustrate that the average household size is as low as 3.09, lower than 10 years ago (3.46). And, the number in urban areas is 2.71, lower than towns (3.08) and rural areas (3.34). The solution of whether or which one(s) of grandparents are required, invited, or voluntary to provide childcare in different families are various. The tradition of prioritizing paternal above maternal relations may be loosening. Besides, because of the gatekeeping role of mothers, maternal grandmothers might be more common in providing childcare than paternal grandmothers. Yet, no study has investigated the cross-cultural difference on biased grandparental investment between WEIRD and Chinese urban samples.

Conclusion

Humans are cooperative breeders. Investment from grandparents (or other alloparents) benefits children’s and grandchildren’s welfare. And, expanding urban market economies and fast-rising maternal employment across the globe

have amplified the need for families to find grandparental investment. Although the evolutionary perspectives have tried to ultimately interpret the biased grandparental investment, the socio-structural benefits of grandparental investment are culture-dependent. Cross-cultural approaches are complementary to evolutionary perspectives (Coall and Hertwig 2010); cross-sociocultural research on grandparental investment should be furthered.

Definition

Culture has also been defined according to various dichotomies, e.g., individualism/collectivism loose/tight cultures; low-context/high-context communication. However, it should be noted that all cultures exhibit both ends of these continuums. All cultures exist along the entire continuum; therefore, all cultures show similarities in the broader scheme of culture. This broader scheme of culture is in essence human nature, human society, and human culture.

Introduction

Defining culture is a complicated endeavor given its variation across domains and purpose, which is embodied within a historical context. An anthropological definition of culture is “...that complex whole which includes knowledge, belief, art, law, morals, custom, and any other capabilities and habits acquired by man as a member of society” (Tylor 1871, p. 1). Culture has also been defined according to various dichotomies, e.g., individualism/collectivism (Gudykunst 2003; Ting-Toomey and Chung 2012; Triandis 2001); loose/tight cultures (Carpenter 2000; Gelfand et al. 2011; Parker et al. 2009; Realo et al. 2014); low-context/high-context communication (Brice 2002; Ting-Toomey and Chung 2012); and/or horizontal/vertical cultures (Triandis 2001).

The continuum of individualism/collectivism revolves around whether the culture places focus on the individual (“I” culture) vs. focus on the

group (“We” culture). Loose cultures display freer definitions of acceptable behavior and have higher tolerances for aberrant behaviors (Gelfand et al. 2011). Loose cultures are most often associated with individualistic culture. However, tight cultures display strong distinctions between in-group and out-group memberships and are most often seen in collectivistic cultures (Gelfand et al. 2011). Low-context communication relies more on messages conveyed (i.e., the words that are said or words in print) than environmental context, while high-context communication relies more on context and the clues for interpretation which can be tangential or indirect (Hall 1983). Meanwhile, horizontal cultures emphasize equalness and individuals holding similar status in society, while vertical cultures place an emphasis on rank and privileges of rank within society (Triandis 2001). However, it should be noted that all cultures exhibit both ends of these continuums. All cultures exist along the entire continuum; therefore, all cultures show similarities in the broader scheme of culture. This broader scheme of culture is in essence human nature, human society, and human culture.

Assimilation Versus Acculturation

Human nature, society, and culture all encompass the use of language to communicate, religion, education, government (or societal leaders), mores, and societal norms. All cultures exhibit traits from both ends of the above mentioned continuums (individualistic/collectivistic, loose/tight cultures, low-context/high-context communication, and horizontal/vertical cultural traits).

What happens when a person develops and grows up in one cultural context and immigrates into another cultural context (e.g., moving from one cultural group to another)? When a person immigrates to another country, two major forces are at play with regards to the degree to which an individual will change and conform to the dominant culture (assimilation) or retain their own cultural identity (acculturation) while accommodating to the dominant culture. Cultural similarities are those attributes which overlap and do not

cause cultural dissonance or cultural interference when the two cultures interact. Hence, this entry will further examine cross-cultural similarities with regard to acculturation and consonance.

Cross-Cultural Similarities

According to Muhammad et al. (2016), stated that “... assimilation occurs when individuals reject their minority culture and adopt the cultural norms of the dominant or host culture” (p. 368). Acculturation comes about when individuals function in the dominant culture while retaining their original culture. Hence, there exists a continuum of cultural adaptation from assimilation to acculturation. Figure 1 illustrates assimilation, whereas, the prevailing culture two (C2) retains dominance over culture one (C1). This has also been referred to as an unidimensional model (Gordon 1964). Rhee (2019) stated that, under assimilation “...immigrants are expected to renounce their ethnic culture and get assimilated to the host culture” (p. 862). Whereas, under acculturation, no one culture retains dominance (See Fig. 2). Acculturation has also been referred to as a bidimensional model. In Fig. 2, the overlap of cultures one and two is evidence of cultural similarities.

Berry’s (1997) theoretical framework of acculturation is the leading theory that explains these processes and acculturation strategies that people employ when adapting to a different cultural environment. Berry (1997) delineates four strategies that a person or group employs when

Cross-Cultural Similarities, Fig. 1 Assimilation

Cross-Cultural Similarities, Fig. 2 Acculturation

acculturating to a new environment depending on whether: (a) the person belongs to the prevailing or to the non-prevailing group; (b) the extent to which the person maintains their cultural heritage referred to as cultural maintenance; and (c) the extent to which a person is in contact with other cultural groups or with their own cultural group referred to as contact and participation (Berry 1997).

The strategies are *assimilation*, *separation*, *integration*, and *marginalization*. *Assimilation* is when a person may conform to the mainstream culture at the expense of forgoing their own cultural identity. An example of *separation* is when an individual maintains their own cultural identity and avoids interacting with others from the dominant cultural group. Maintaining one's cultural identity while interacting with the prevailing group is referred to as *integration*. Rhee (2019) stated that, "Contrary to separation and marginalization, when immigrants effectively interact with the American society, their acculturation strategy can be defined either as integration with their adherence to their ethnic culture or as assimilation with low adherence to their ethnic culture" (p. 862). First generation immigrants are more likely to hold strong ties and adherence to their own culture (Rhee 2019). "*Integration*" is Berry's term; however, this is also referred to as acculturation by others. This entry will use the term "*acculturation*" since it is a more accepted and widely used term.

Marginalization is when an individual has no interest in maintaining their own cultural identity and interacts with the prevailing cultural group as a result of enforced cultural loss and discrimination. Of these strategies, research has documented that acculturation or biculturalism by others, is an

adaptive strategy associated with positive effects (Berry 1997). That is, one is able to maintain one's own cultural similarities and differences.

Employing an acculturation strategy depends on a number of factors such as whether the dominant cultural group is willing to accept non-prevailing groups into society, whereupon access to equal rights, such as education, healthcare services, job opportunities, are provided (Berry 1997). *Acculturation*, however, is only possible if the prevailing society values cultural and linguistic diversity, and also shows minimal prejudice, racism, and discrimination, i.e., positive mutual respect toward others and espouses a viewpoint that all cultural groups are part of a larger society (Berry and Kalin 1995). Also, the non-prevailing cultural group incorporates the values of the prevailing cultural group in their cultural schema. Consequently, a person from a non-prevailing cultural group that uses an acculturation strategy may show less acculturative stress and demonstrate more positive outcomes (Ehlers et al. 2009). Therefore, individuals from a nondominant cultural group may be less prone to depression and anxiety, and may be able to successfully maneuver between the dominant and nondominant culture (Mui and Kang 2006).

The least adaptive of these acculturation strategies is *marginalization* that has been linked to psychopathology and poor physical health outcomes, academic and work performance, as well as delinquency in immigrant youth (Ungar 2015). Acculturative stress occurs when a person experiences difficulties adapting to their new environment. This includes adapting to new standards, rules, behaviors, language, value system, dressing, eating, and ways of doing things. Typically, a person has a coping mechanism that allows them to overcome these difficulties and adapt to their new environment. However, when a person is marginalized or does not belong to either the dominant or non-dominant group (or in instances of high acculturative stress, i.e., stress encountered when changing from one cultural group to another (D'Anna-Hernandez et al. 2015)), clinical depression and anxiety may ensue (Burrow-Sánchez et al. 2015).

Research in acculturation points to the benefits of incorporating an integrative or bicultural

strategy in which a person integrates knowledge of cultural beliefs and values, positive attitudes towards both cultures, bicultural efficacy, bilingualism, and a repertoire of adaptive behaviors or roles (LaFromboise et al. 1993). Competencies in these various areas, a bicultural person is “grounded” or has developed a strong social capital that can be utilized in times of stress and adversity. Hence, the successful bicultural individual has reduced ambiguity, shown resilience, and is able to navigate between the two cultures with ease, i.e., able to navigate among culture one, the shared culture similarities, and culture two.

Conclusion

Cultural awareness and knowledge about the history, various institutions, social interactions, religious beliefs, gender roles, and practices of everyday life of both cultures allow one to navigate competently between cultures. Positive attitudes toward both groups facilitated by frequent contact and exposure reduce stress and conflict. This in turn builds self-efficacy to live within two cultures without losing one's own identity. In sum, biculturalism promotes cultural similarities to exist and to thrive.

present in a feminine/transgender manner and are recognized as members of a “third” gender, known locally as *fa’afafine* (see ► “Fa’afafine”). Here, quantitative research pertaining to two evolutionary hypotheses for male androphilia that have been tested in Samoa is reviewed (also see, ► “Kin Selection Hypothesis”).

Models of the Ancestral Form of Male Androphilia

VanderLaan et al. (2013) found that the conditions that typify the ancestral human sociocultural environment (e.g., small community size, dependence on hunting and gathering, egalitarian political structure, and animistic belief systems) were more prevalent in cultures in which androphilic males presented in a feminine/transgender manner, compared to cultures in which they did not. This suggests that the feminine form of male androphilia is evolutionarily ancestral to the masculine (“gay”) form. The outcome of evolutionary processes may be obscured when examining more derived forms of male androphilia (e.g., the masculine, “gay” form), which may reflect historically recent cultural influences. Consequently, feminine androphilic males likely represent better models for understanding the evolution of male androphilia.

Sexually Antagonistic Gene Hypothesis

Sexually antagonistic selection is a form of balancing selection that occurs when genetic factors that produce fitness costs in one sex result in fitness benefits in the other sex. The Sexually Antagonistic Gene Hypothesis for male androphilia (SAGH) posits that genes associated with the development of androphilia result in decreased reproductive output in male carriers, but the same genes result in increased reproductive output in female carriers. Given that kin share a disproportionate number of genes in common, the female kin of androphilic males should experience, on average, increased reproductive output than females with no androphilic male relatives.

Cross-cultural comparisons; Cultural studies

Definition

Cross-cultural study involves examining human behavior across various cultural settings to elucidate human behavioral similarities and differences. Cross-cultural comparisons are particularly useful in the field of psychology, because they enable researchers to parse apart which features of human behavior can be attributed to unique social or environmental factors and which features reliably emerge regardless of context.

Introduction

A considerable portion of the cross-cultural evolutionary research on male androphilia (i.e., male sexual attraction to adult males) has drawn comparisons between Canada, Italy, and Samoa, a small Polynesian island nation in the south Pacific. In Samoa, androphilic males publically

In theory, the fitness benefits accrued to the female relatives of androphilic males balance out the fitness costs associated with male androphilia. Consequently, the sexual antagonistic selection of these genes occurs because of their fitness-enhancing properties in female carriers. A by-product of this sexually antagonistic selection is that male androphilia persists in populations over evolutionary time, despite its fitness-reducing consequences. Given all this, the basic prediction that flows from the Sexual Antagonistic Gene Hypothesis is that the female relatives of androphilic males should tend to produce more offspring than those of gynephilic males (males who are sexually attracted to adult females). Additionally, because females are conferred the benefit, it has been suggested that the genes underlying male androphilia should be present on the X-chromosome (Camperio-Ciani et al. 2004).

Samoa represents an optimal location in which to test the SAGH, because the population is characterized by higher fertility when compared to Western European and North American populations (Central Intelligence Agency 2012). Individuals in low fertility populations often employ methods to limit reproduction, which artificially lower women's fertility. In addition, the purported ancestral form of male androphilia – the transgender form – predominates in Samoa (VanderLaan et al. 2013).

Four studies have been conducted in Samoa that furnish data pertaining to the SAGH. Vasey and VanderLaan (2007) demonstrated that the mothers of *fa'afafine* produce more offspring than those of gynephilic men. VanderLaan and Vasey (2011) replicated this finding and Semenyna et al. (2017) replicated this finding a third time. VanderLaan et al. (2012) demonstrated that *fa'afafine's* maternal and paternal grandmothers exhibit elevated offspring production. Semenyna et al. (2017) replicated this maternal grandmother effect, but the paternal grandmother effect was not replicated. Due to the more robust sample size employed by Semenyna et al. (2017), which was 77 % larger than the one used by VanderLaan et al. (2012), it is possible that the previously reported paternal grandmother effect resulted from statistical error. If elevated offspring

production is limited to maternal-line female relatives, as Semenyna et al. (2017) study suggests, then it would be consistent with the assertion by Camperio-Ciani et al. (2004) that the purported sexually antagonistic genes influencing the development of male androphilia are located on the X-chromosome.

Elevated reproduction by the mothers and the maternal grandmothers of *fa'afafine* does not provide definitive support for the X-linkage of sexually antagonistic genes, because reproduction by these categories of female kin is naturally confounded with that of fathers and grandfathers, all of whom share genes with androphilic and gynephilic male probands. Instead, elevated reproductive output by androphilic males' maternal aunts, paternal aunts, or both would provide the clearest support for the SAGH, because androphilic and gynephilic male probands do not share genes with their aunts' male reproductive partners. To date, cross-cultural research in Samoa has consistently failed to find such aunt effects (VanderLaan et al. 2012; Semenyna et al. 2017). Further, evidence for this effect among aunts has been limited to samples of men pooled from Western Europe (e.g., Camperio-Ciani et al. 2004).

Balanced Polymorphism Hypothesis

The Balanced Polymorphism Hypothesis for male androphilia (BPH) takes as its starting point the assumption that male androphilia is not an isolated trait but, rather, is part of a larger package of gender-atypical traits. Ample empirical evidence exists to support this assumption (Bailey et al. 2016). Miller (2000) proposed that multiple genes influence the development of male androphilia, and these genes shift male brain development in a female-typical direction. Males who inherit a critical number of these genes become androphilic. Below this critical threshold, males who inherit some of these genes are gynephilic, but are feminized in terms of certain personality traits, which render them more sensitive, empathetic, tender, and kind. These personality traits, in turn, are thought to render

gynephilic males more attractive as mates. Indeed, ample empirical evidence exists to support this assumption (e.g., Buss and Shakelford 2008). Owing to their increased attractiveness, Miller (2000) argues that these males obtain more female sexual partners and father more children compared to gynephilic males who have no androphilic male relatives. These males are also hypothesized to be better fathers compared to fathers with no androphilic male relatives. The increased reproductive success experienced by androphilic male's gynephilic male relatives favors selection for the feminizing genes in question. As such, positive selection for these genes occurs despite the reproductive costs associated with male androphilia itself.

A number of predictions flow from the BPH. First, androphilic males are more likely to be feminine than masculine. Second, gynephilic males should be more feminine if they have androphilic male relatives, compared to those who do not. Third, gynephilic males should be more attractive if they have androphilic male relatives, compared to those who do not. Fourth, gynephilic males should obtain more female sexual partners if they have androphilic male relatives, compared to those who do not. Fifth, gynephilic males should father more children if they have androphilic male relatives, compared to those who do not. Sixth, gynephilic males should be better fathers if they have androphilic male relatives, compared to those that do not.

To date, two studies relevant to testing the BPH have been conducted in Samoa. VanderLaan et al. (2012) found that the maternal and paternal uncles of Samoan *fa'afafine* did not differ from Samoan gynephilic males in terms of their offspring production. In contrast, Semenyna et al. (2017) found that the paternal uncles of Samoan *fa'afafine* fathered more offspring than those of gynephilic males, but the effect size was small raising the possibility that this group difference may reflect statistical error. Taken together, these studies failed to furnish strong support for the Balancing Selection Hypothesis.

Conclusions

Cross-cultural comparisons have been used to study the evolution of male androphilia. This approach has helped establish the optimal population for testing evolutionary hypotheses. Hypothesis testing in relevant cultural contexts has furnished insights into the evolution of male androphilia. Overall, there is support for the SAGH, although more research in additional populations of transgender androphilic males would be beneficial.

Cross-Cultural Universality

Reza Ziai

Psychology, Penn State University, Beaver, USA

Synonyms

Human nature; Human universals; Universalism

Definition

Core mental attributes or psychological traits that are shared, to varying degree, by the vast majority of human beings (Norenzayan and Heine 2005)

Introduction

Despite some controversy (Geertz 1973; Norenzayan and Heine 2005), Donald Brown (1991) constructed a list of hundreds of universal characteristics (e.g., marriage, coalitions, rituals, fear of snakes, etc.) that are common to all known cultural groups. Although aspects of cultural behaviors are often learned, variations in ancestral ecologies across deep time ultimately gave rise to differences in the expression of innate human traits (Diamond 1997). Cultures are essentially adaptive responses to the environmental niche that they each evolved in (Cohen 2001; Boserup 1970; Gilmore 1990).

Cultural Universals

Determining what a cultural universal is depends on the operational definition of *culture* as well as the standards of evidence for such claims. The broader the definition of a psychological trait, like subjective well-being, for example, the greater the likelihood that the trait will be seen universally. However, if the operational definition is narrowly defined to exclude certain situations, the trait in question may be seen to a greater degree in some cultures than in others (English and Chen 2011; Suh 2002). There is no current consensus among researchers for what would methodologically strengthen the case for universality of a cultural trait (Norenzayan and Heine 2005). Generally, however, if the same psychological process exists in two widely divergent cultures, then the case for universality gains more traction. For example, if theory of mind exists in 4-year-old children in urban parts of Philadelphia as well as in 4-year-olds born in the rainforests of Cameroon, the case for universality is strengthened. Indeed, children sampled in Western populations are able to successfully understand another person's differing point of view in a false belief task around the same age as Baka children born in southeast Cameroon (Avis and Harris 1991), thereby supporting the case for universality.

The claim for universality of a cultural trait is further bolstered when multifactorial research methods are used in unison. Physiological studies (Way and Lieberman 2010), fMRI research (Hedden et al. 2008), self-reports (Miller et al. 2011), and animal studies (Nagell et al. 1993) have all been used to make the argument that cross-cultural universals do in fact exist. Take, for example, social facilitation or the notion that organisms tend to perform better on simple tasks in the presence of observers. Although disagreement about its innate origins exists (Do-Yeong and Junsu 2010), social facilitation has had supportive evidence in humans in a natural setting (Michaels et al. 1982), cockroaches (Zajonc et al. 1969), and macaques (Dindo et al. 2009).

Even in the presence of universality, there often exists a host of variations that some would rather not like to think of all too clearly. Incest avoidance is one such trait. From a genetic standpoint, it makes sense to avoid having sex with relatives (Westermarck 1922). This is one reason why it is standard practice in many households to separate girls' rooms from boys' rooms. But as universal as incest avoidance seems, the way bedrooms are set up differs in homes in Chicago compared to homes in Orissa, India (Shweder et al. 1995). Both populations value incest avoidance equally, but the next most important thing in Western homes is what Richard Shweder and his colleagues called "the sacred couple," whereas in Hindi homes it was "protection of the vulnerable."

The debate over whether incest avoidance is a human universal or not has led one researcher (DeMause 1991) to go so far as to make the exact opposite claim: that incest (and *not* its avoidance) is universal. The point here is that universals do exist, but what they are and to what degree they manifest themselves are often contentiously debated (Norenzayan and Heine 2005). The debate over the universality of psychological traits has lent itself to bitter acrimony over some of the most commonsense notions. Take, for example, when Paul Ekman showed that facial expressions are understood worldwide. He was called a racist and his idea (as unifying as it seems) was considered appalling by many. One of Ekman's own colleagues shouted at him in a

conference calling his ideas "fascist" (Pinker 2002).

Making the case for universality is often rife with friction when certain topics are investigated. Consider the research showing that male and female humans tend to guard their mates from mate poachers. In Western societies, methods of mate retention and guardianship vary within and between genders ranging from vigilance to violence (Buss 1988). In addition to this, there are cross-cultural differences seen as well. In many Muslim majority countries, for example, the hijab and other forms of guardianship have been used to keep poachers at bay and to preserve chastity and virginity. In fact, when environmental pressures increase, as one would predict (see next section), stricter mate-guarding practices are employed in the form of religious veiling (Pazhoochi et al. 2017). Mate guarding is seen throughout the animal kingdom as well including but not limited to giraffes (Bercovitch et al. 2006), jumping spiders (Elias et al. 2014), and the blue crab (Jivoff and Hines 1998).

To sum up, evidence from cross-cultural psychology as well as ethological studies support the idea that innate psychological traits exist in humans. It is clear that many hundreds of these human generalizations exist (Brown 1991), but what is also incontrovertible is the rich variation in the expression of these cultural traits.

Context Matters

There is a common misconception among social scientists who believe evolutionary psychology posits that psychological adaptations are solely determined by genes. Nothing could be further from the truth, and, in fact, many evolutionary theorists spend considerable portions of their careers refuting such misattributions. Evolution is not merely driven by incremental genetic mutation. Evolution is genetic mutation *plus natural selection* (Dawkins 1976). Similarly, evolutionary psychology is not simply about biological mechanisms; it is also about the environmental pressures that selected for these adaptations in the first place (Al-Shawaf et al. 2019; Cohen 2001). It was

not Darwin's "theory of evolution" but rather his "theory of evolution by natural selection" that he (and not Alfred Russel Wallace) was eventually given credit for (Schultz and Schultz 2012).

Indeed, the composite forces that shaped individual traits across deep time are discussed in such depth (Buss 1999) that evolutionary theorists have even provided specific nomenclature for it in order to test their hypotheses. The *environment of evolutionary adaptedness* (EEA) is the combination of elements that selected for certain traits (Tooby and Cosmides 1992). The EEA is not confined to one single place or time but rather refers to a host of environments of change. Whether the focus is on the evolution of bipedal locomotion, how humans moved from hunter gatherers to agrarian societies, or the many forms of eyes that evolved on our planet, evolutionary psychologists have long maintained that context plays a crucial factor in the selection of phenotypes – both physical and behavioral.

Cultural Variation

Why is it that some cultures, like the Sambia of Papua New Guinea, are still tilling the earth with stone tools while Europeans along the Franco-Swiss border are smashing subatomic particles at CERN? On the surface, this question may seem like a joke made in poor taste or a trope that could ultimately wax into unfalsifiability and the jingoistic rhetoric of Manifest Destiny. This is hardly a joke. In fact, this question is a complicated one and has been put forth in a different form by Jared Diamond in his Pulitzer Prize winning book, *Guns, Germs, and Steel* (1997). In it, Diamond investigated why it was the Spaniards who invaded the Americas and conquered the Incans and not the other way around.

To those who wrongly adhere to the Myth of the Noble Savage (Pinker 2002), the explanation would be that the Incans were peacefully living in harmony with nature and therefore had no desire to invade anyone. The evidence obviously contradicts this supposition when one takes even a cursory glance at the Incan's military campaigns (Espinoza 1981). On the other hand, a biological

determinist might say that the Incans had "inferior genes" and, as a result, were unable to develop the cultural tools necessary to cross the Atlantic and slaughter the Spaniards. However, this idea also collapses when scrutinized. The genetic differences between Incans and Spaniards are relatively small and could not by themselves account for such vastly disparate cultural adaptations (Heine 2008).

Learned Is Not the Opposite of Evolved

Given that the context a trait evolves in matters tremendously in the outcome of phenotypes (with "culture" being very broadly defined as a phenotype) and that variation in cultures exist around the world, questions arise: Why does culture vary at all?

It often is stated by anthropologists and cultural relativists that cultural variation exists simply because things are learned. But this is only partially correct. The mistake in labeling something as "learned" or "evolved" comes from ignoring whether one is looking at a psychological trait from a proximate lens or a distal one. For example, from a proximate point of view, we know that Pizarro defeated the Incans because his men had horses, rapiers, and muskets. From a distal point of view, the reason his men possessed these items (as well as resistance to certain germs) and Atahualpa's men did not, had to do with the abundance of wheat, grain, barley, and livestock that Pizarro's ancestors evolved in (i.e., their *EEA*) (Diamond 1997).

According to Diamond (1997), the origins of inequality have had less to do with simply having the right ideas as they have with the ancestral ecology one's people evolved in. Claiming that variation in cultural values and beliefs are simply the result of bad ideas versus good ideas would be committing the blank-slate error. Ecological variability in the environment, plus sociocultural input mechanisms, combined with the interaction of innate psychological primitives across deep time has yielded "if-then" strategies (Norenzayan and Heine 2005). In short, different environments have yielded different cultures

where innate psychological mechanisms were selected for by the environment. More specifically, the brain is a biological organ designed by natural selection to extract information from different environments ultimately giving rise to different cultures with similar core underpinnings (Al-Shawaf et al. 2019; Cohen 2001).

While common universal traits exist, ecological forces are known to have tailor-designed sociality across a broad range of biological taxa. For example, when cross-cultural psychologists have looked at gender and the division of labor across cultures and time, it is clear that those cultures that evolved in benign environments have more egalitarian gender roles than those that evolved in harsh environments (Alesina et al. 2013; Boserup 1970; Cohen 2001; Gilmore 1990). The environment has also played a key factor when researchers looked at culture of honor (Nisbett and Cohen 1996; Shackelford 2005), the varying degrees of penalty high moralizing gods mete out to transgressors (Botero et al. 2014), and human mating strategies (Buss 1999).

Conclusion

Thought experiment: imagine if we sent a spaceship with a load of microorganisms across the cosmos. This is precisely what Francis Crick and Leslie Orgel had proposed in 1973. Imagine this pod of genetic material landed on three different planets with slight variations in their ecologies. What would one expect to see over time? The most likely prediction from this is that organisms would evolve on those planets making them all alike and all different. They would be all alike because the origins of their genetic makeup were from a common source. And they would all be different simply because the ecologies that the genetic seeds evolved in across deep time allowed for variation in the affordances provided to those organisms. Hence, the environments on these hypothetical planets would select for different genetic traits ultimately leading to variations in culture. It would be erroneous to conclude that variations in cultures that existed on these planets

were simply due to learned behavior without taking into account genetic similarity as well as ecological variation.

Cross-Cultural Variation

Alejandro Brice

University of South Florida St. Petersburg,
St. Petersburg, FL, USA

Synonyms

Cultural differences; Cultural heterogeneity;
Multi-cultural

Definition

Cultural variation is the degree that one culture differs from another on any continuum of comparison. It is best to think of these continuums as ranges of behavior; i.e., no one culture or person exclusively exhibits one end of the continuum. Variations may exist on any number of levels.

Introduction

Defining culture is a complicated endeavor given its variation across domains and purpose,

which is embodied within a historical context. Roseberry-McKibbin (2007) defines culture as, “Simply, culture is a dynamic set of values and belief systems that shape the behavior of individuals from various groups and communities” (p. 104). Hence, culture shapes how people live, interact, and interpret the world around them as well as what people value. For example, one culture may value independence and autonomy, while another values dependence and cooperation. Culture or shared patterns of behaviors, thoughts, feelings, attitudes, and values may differ according to membership of racial, ethnic, religious, or social groups (Zion and Kozleski 2005). Furthermore, culture can also differ between gender, class, physical and mental abilities, religious and spiritual beliefs, sexual orientation, and age.

What Is Culture?

Culture can be defined according to various continuums of behavior, individualistic versus collectivistic cultures, loose cultures versus tight cultures, low-context versus high-context communication styles, and horizontal versus vertical cultures (Triandis 2001). These continuums are not absolute; for example, individuals from collectivistic cultures can display behaviors that are individualistic. Cultural variation is the degree that one culture differs from another on any continuum of comparison. It is best to think of these continuums as ranges of behavior; i.e., no one culture or person exclusively exhibits one end of the continuum. Variations may exist on any number of levels.

Individualistic Versus Collectivistic Cultures

Individualism is the broad value of tendency of a culture to emphasize individual over group identities, individual over group rights, and the individual’s personal needs over a group’s needs (Ting-Toomey and Chung 2012), whereas collectivism, on the other end of the spectrum, refers

to broad tendencies of a culture to emphasize the value of the “we” group identity over the “I” individual identity. Group obligations dominate over an individual’s rights, and in-group-oriented needs are seen as more important than any individual’s wants and desires.

Individualistic cultures define the self apart from the group and as independent. The focus tends to be on the person and not so much on the group (Ting-Toomey and Chung 2012). Individualistic cultures explain one’s behaviors on personal attributes, e.g., Fernando seeks the teacher’s approval because he needs reassurance. Individualistic cultures tend to stress the “autonomous self” (Ting-Toomey and Chung 2012), where one portrays oneself outward, and face is self-oriented and self-driven (Triandis 2001). Individualistic cultures stress direct and overt communication. An example of overt and direct communication is seen in the “get to the point” style of speaking.

In comparison, collectivistic cultures value a more indirect style of communication, an emphasis on social interactions, and avoidance of confrontations. Confrontations are seen as loss of face. Belonging to the group is a main tenet of collectivistic culture (Gudykunst 2003; Triandis 2001). Cohesion and group participation are of utmost importance (Brice and Campbell 1999). Behaviors are explained by norms or standards of expected behavior, e.g., Fernando seeks teacher approval in order to belong to the group. “Face” is important in group cultures which emphasize group orientation (Gudykunst 2003). Membership in group cultures permits the right to be involved in the affairs of others; e.g., uncles, aunts, grandparents, teachers, or professionals may mediate on another’s behalf. Latino cultures, Asian cultures, Middle Eastern cultures, African cultures, and others exemplify collectivist cultures.

Loose Versus Tight Cultures

Cultures that have strong societal norms with low tolerances for aberrant behavior are defined as tight cultures (Carpenter 2000; Gelfand et al. 2011; Parker et al. 2009; Realo et al. 2014). Tight

culture and group cultures (i.e., collectivistic) have strong distinctions between in-group and out-group membership. Loose cultures typically have weak norms with high tolerances for aberrant behaviors (Gelfand et al. 2011).

Individualistic cultures are associated with loose cultures, whereas tight cultures are associated with collectivistic cultures (Brice and Campbell 1999). Looseness carries the substance of creativity. This is seen in language in word puns and humor. However, it should be noted that not all cultures will exhibit all behaviors consistent with either end of the individualistic/collectivistic or tight/loose continuums. For example, Cuban culture exhibits traits of creative language use with puns and witty language; however, Cuban culture tends to display itself along collectivistic and tight ends of the culture continuums (Brice 2002).

The USA is seen as a loose culture, while Japan is considered to be a tight culture (Gelfand et al. 2011). Whitting (1989) compares Japanese and US American in-group versus out-group cultures. He uses American versus Japanese baseball as cultural contrasts. Whitting (1989) stated that “All the managers manage differently here. I mean they manage Japanese style. And I do it more or less U.S. Style. So I’m the one that’s different really” (p. 143). Whitting emphasizes this point by stating that, “Many Japanese will argue that a foreigner should never be allowed to manage a Japanese baseball team” (p. 143).

Low-Context Versus High-Context Communication

The concepts of low-context and high-context communication were first introduced by Hall (1983). Low-context communication relies less on environmental context for interpreting the meaning of the message; instead, most of the message is in the spoken or printed words (e.g., print or formal communication such as speeches). Interaction between the speaker and listener tends to be minimal. Low-context communication is evidenced by logical and linear thoughts. Direct verbal and nonverbal interactions, overt

communicative intentions, and sender-oriented values are seen in low-context communication and typical in individualistic cultures (Ting-Toomey and Chung 2012). Low-context cultures tend to attribute behaviors to the individual’s personality, e.g., “That is just Charlie.”

High-context communication attributes behavior to an external locus of control or where one places responsibility for actions and to societal norms (Brice and Campbell 1999). One acts according to norms of how one is supposed to behave. High-context communication uses indirect styles of speech and includes multiple tangential, indirect conversations. The tangential conversations are seen to add to the big picture of the communication, i.e., relevant to the general message. Communication is achieved via verbal negotiations and use of subtle nonverbal nuances. Low-context communication messages are direct and “to the point.” Brice (2002) stated that Cuban-Americans exhibit a more indirect communication style. Discussion of family, friends, employment, etc. almost always precedes the main intent of the message.

Horizontal Versus Vertical Cultures

Culture can also be defined according to the horizontal versus vertical continuum. Group or individualistic cultures may either be horizontal or vertical on this continuum. The horizontal perspective emphasizes that individuals are similar and equal on most aspects especially that which involves rank or status; hence, this perspective emphasizes sameness. The vertical perspective emphasizes rank and privileges of rank even if inequalities associated with rank are present (Triandis 2001). Hence, this perspective emphasizes difference. Therefore, when the collectivistic-individualistic continuum is combined with the horizontal versus vertical continuum, then there are four possibilities: (a) collectivistic horizontal (group/same); (b) collectivistic vertical (group/rank and difference); (c) individualistic horizontal (individual/same); and (d) individualistic vertical (individual/rank and difference).

Individuals from a collectivistic horizontal (group/same) culture stress group values, social cohesion, cooperation, and equality among members. Israeli kibbutzim members both are group oriented and stress membership equality.

Collectivistic vertical cultures which are group/difference oriented show traits of belonging to a group yet maintain clear class and rank differentiations. In Japanese language and culture, the word and concept of “*giri*” signifies obligation, honor, duty, and burden. One is obligated to the group and also bound to superiors in completing one’s honor (i.e., especially to the family and to elder) over one’s individual wishes and desires. A rank model is also evident in language and the honorifics or etiquette in how one addresses others. One address others based on their rank, status, and/or hierarchy in relation to oneself. In Japanese, one may add the affix “*san*” to another person’s name that is at the same level as oneself. “*Sama*” is generally reserved for elders, especially family members (e.g., *otosama*, father; *okasama*, mother). “*Chan*” may be used as endearment for children. “*Sempai*” (mentor) is used for those with seniority, typically in workplaces. However, “*kouhai*” means the opposite of “*sempai*” denoting someone of a lower ranking. In addition, it is considered rude to employ such terms when speaking with those individuals.

Individualistic horizontal cultures (individualistic/same) place emphases on uniqueness and sameness. Sweden and Finland are examples. All individuals are seen as the same; therefore, there is no need for formal communication. What may be seen as intrusive in a rank-oriented culture is seen as typical in a horizontal culture. Living independently is a valued trait. Parents and grandparents do not live with their offspring children. Individual horizontal cultures are often seen in democratic socialistic governments (such as the Scandinavian countries).

Individualistic vertical cultures (individual/rank) focus on self-achievements and obtaining higher status. Individuals behave in ways to be recognized on one’s merits, especially if that places one at a higher social status. Taking

“selfies” and/or posting on social media illustrate the importance of the individualistic culture and how to stand out from others. Rank is evidenced in the form of titles (e.g., Instructor, Lecturer, Assistant Professor, Associate Professor, Professor). The CEO of a company or Dean of a College have the expected honor of having more “talk-time” in a meeting than employees or subordinates. Those in superior positions may be more direct or blunt in communications.

Culture and Language

The separation of cognition and language and how language is acquired is still debated. However, most researchers will agree that cognition and language are intertwined to some extent (i.e., whether a weak or strong connection exists). The role of language and culture has also been extensively disputed. The theory of linguistic relativity is discussed next.

The theory of linguistic relativity suggests that language affects how individuals see and construct their world (Hill and Mannheim 1992; Lucy 1997). Lucy defines linguistic relativity as, “The linguistic relativity hypothesis, the proposal that the particular language we speak influences the way we think about reality, forms one part of the broader question of how language influences thought” (p. 291). Linguistic relativity evolved from the earlier works of Benjamin Whorf (Whorf 1956). Whorf believed that difference in language grammars and how the languages are used affects the manner and way in which the speakers perceived the world and their environment. One can postulate that language is constructed and learned and, therefore, a reflection of culture (Lucy 1997).

Conclusion

Everyone possesses a unique cultural mosaic made up of different attributes. Whether one is collectivistic or individualistic; displays an internal versus external locus of control; is male or

female; is young, middle-aged, or old; is from low, medium, or high SES; or is short or tall makes everyone different. Our cultural mosaic makes us culturally unique. As educators, we need to realize the rich mosaic tapestry of who we are, and this is how culture should be viewed for everyone and not just for certain ethnically diverse individuals. This reminds us that stereotypes and biases can be reduced with greater awareness of cultural differences. However, it should be noted that no one culture or person exclusively exhibits one end of the continuums that have been examined (or any others) and that these continuums, as ranges of behavior, are not absolute.

Definition

Welling of tears or shedding of tears from the eyes in response to internal emotional states, often accompanied by vocal emissions, irregular and interrupted breathing, and tremors.

Introduction

Tear or lacrimal fluid is produced in the lacrimal glands, situated above each eye and slightly askew to the side of the head. The tears moisture and lubricate the eye bulb, and their excess is drained into the nasal cavity through the *lacrimal canaliculi* at the upper and lower eyelids, close to the nose. Thus, both increased production and decreased evacuation of tear fluid result in visible wetting of the eye, eyelids, or cheek. To cry means literally to produce loud vocal sounds (from French *crier*, from Latin *quiritare*; to wail), while the term for shedding tears specifically to express grief or some other emotion is weeping (e.g., Chambers 2019), as noted by Bellieni (2017). To some confusion, crying colloquially and contemporarily designates weeping. These terms will be used interchangeably while noting that the term crying is more common and more explicitly implies the vocal emissions that are often and typically associated with weeping as an emotional expression. The pure shedding of tears regardless of cause and function seems therefore to be reserved for the technical term lacrimation, which may occur as a reaction to physical or chemical irritants, like smoke.

These functions and their etiology largely remain a mystery, although some general patterns have been established (for reviews see, e.g., Vingerhoets et al. 2001). Crying is very common throughout infancy and childhood and then drastically decreases in adolescence. Most people weep occasionally in adulthood, females much more often than males, but the individual differences are huge. In fact, the frequency of weeping may be the largest psychological sex difference, where females weep between four (Frey et al. 1983) and seven times more often (Kraemer and Hastrup 1986). Likewise, females tend to weep for longer periods than men and tend to be more prone to flowing tears and sobbing, whereas males more often become lachrymose without actually shedding tears (Bindra 1972). Another entry is devoted to sex differences in crying (Madison and Dutton 2019). Crying increases again in late adulthood and in old age, while the sex difference decreases. One study found that in their 40s, males

had cried on average 5.5 times and females 29.3 times in the last 12 months, whereas in a group approaching 70 years of age, the frequencies were 16.3 for males and 31.1 for females (Hastrup et al. 1986).

Crying is elicited by the sympathetic system, which prepares the organism for fight or flight and which typically also causes increased arousal, heart rate, and sweating, as well as slowed breathing. Side effects of crying are partly caused by the sympathetic response, such as quivering lips, cracking voice, and the sensation of a lump in the throat. This so-called globus sensation is caused by trying to close the *glottis* (ultimately to prevent food from entering the *larynx*), while the sympathetic response expands the glottis to increase airflow. Another side effect is that the flow of excess tears through the *lacrimal canaliculi* makes the nose run. The lacrimal system and its reflexive responses to irritants is present in many species, but in humans it also serves functions of emotional processing and social communication. There are anecdotal observations of lacrimation for some mammal species in situations likely to evoke emotions related to sadness and loss, but the evidence for weeping in nonhuman animals is weak (Frey and Langseth 1985).

Functions of Crying

One of the things we know is that crying is associated with sadness or grief, such as when mourning the death or illness of a loved one. The most important thing to know, however, is that crying is a complex, multifaceted phenomenon that exhibits many inconsistencies. Thus, people do not always weep when they are sad, and they do sometimes weep for quite different reasons. In a sample of 800 weeping episodes in typical women, 49% were associated with sadness, 21% with happiness, 10% with anger, and 7% with sympathy, and the remaining 13% were rather evenly distributed across anxiety, fear, and “other” (Frey et al. 1983). Inferred causes for crying in infancy include fatigue, hunger, fear, and loneliness (Catherine and Schonert-Reichl

2011), while self-reported reasons for adult crying include problems with interpersonal relations, sad thoughts, and media. Media refers mainly to fiction, such as movies and TV series, and accounts for about one third of all weeping episodes for both sexes (Frey et al. 1983). Four factors in particular should be considered in order to understand group differences in crying, namely, the exposure to emotional stimuli, the appraisal of these stimuli, social learning, and the threshold for beginning to cry (Vingerhoets et al. 2009, p. 451). Whether crying occurs in response to a certain event or emotional state furthermore depends on many other factors, such as one’s age, sex, being alone or in the company of others, one’s relation to those other people, and so forth (Vingerhoets et al. 2001). It is therefore not surprising that a range of quite different functions and theories for crying have been proposed.

Some of them focus on intraindividual functions, where the physiological processes of crying somehow lead to relief and recovery from distress, regardless of its origin being within or outside the individual (Frey et al. 1983; Stougie et al. 2004). More specifically, crying has been conceived of as part of a two-stage process, where it is preceded by a buildup of arousal, tension, or anticipation, which is then alleviated (Efran and Spangler 1979). Several reviews discuss these functions and the evidence for and against them (Rottenberg et al. 2019; Stougie et al. 2004; Vingerhoets et al. 2009).

Other theoretical explanations focus on inter-individual functions in terms of communication and social support, as reviewed by Bellieni (2017), Miceli and Castelfranchi (2003), and Vingerhoets et al. (2009). A recurrent theme is that crying ultimately signals helplessness and so prompts help and support from others (Miceli and Castelfranchi 2003). This should be seen in light of the fact that more than 70% of respondents rated that they were most likely to cry alone, at the same time as they were next most likely to cry in the company of a close female friend (said 53% of males and 86% of females) (Lombardo et al. 2001). Consistent with the help-seeking hypothesis, respondents reported that they would give more emotional support to and express less

negative affect toward a weeping person (Hendriks et al. 2008).

Finally, tears are elicited in response to certain profound experiences, such as religious fervor and appreciating the aesthetic beauty of works of art in painting, poetry, music, and sculpture, for example, although the explanation for this is unclear (but see Miceli and Castelfranchi 2003).

Etiology of Crying

As mentioned it is unclear if weeping occurs in any species except humans (Vingerhoets et al. 2009, p. 440). None of several suggested explanations has received convincing support. One example is that the smoke from fire used in funeral cremations or farewell ceremonies caused lachrimation, which led to associating tears with sadness and loss. This seems implausible because smoke would have occurred much more often in daily activities also associated with stress and stress relief, like cooking and keeping warm, without those becoming associated with tears (see Bellieni 2017).

Conclusions

Crying is a human universal and most likely an evolutionary adaptation, although its ultimate adaptive value and etiology remain poorly understood. Cross-cultural surveys exhibit similar patterns, most prominently that females cry more than males and that respondents report feeling better after crying (Becht and Vingerhoets 2002; Rosenblatt et al. 1976). The literature contains a wide range of empirical findings, relating crying and crying-related behavior to a host of other variables than those mentioned above. These variables include alexithymia, anhedonia, attitudes toward crying and people who cry, brain structure and brain activation, coping, depression, femininity and masculinity, hormones, individualism and collectivism, mood, and personality traits. They furthermore include shame, socioeconomic status, social connectedness (Vingerhoets et al. 2016),

and national estimates of gender equality/empowerment (Fischer et al. 2004), as well as specific constructs such as affective empathy, cognitive empathy, anxious attachment, and avoidant attachment (Denckla et al. 2014). This means that there exists a nexus of associations with crying and weeping, which taps a wide range of social dimensions, including friendship, family relations, social status, and power dynamics. Because of their large effect size, associations that involve sex differences would be particularly powerful. Thus, this rich nexus may be utilized for assessing evolutionary-based hypotheses that involve interactions between sex, crying, and other social behaviors (e.g., Vigil 2008).

Cryptic Female Choice

Hanne Løvlie

Linköping University, Linköping, Sweden

Synonyms

[Female-biased postcopulatory sexual selection;](#)
[Sperm choice](#)

Definition

A female mate choice occurring during or after copulation.

Introduction

Sexual selection, the selection pressure selecting for traits that increase reproductive success of individuals, can in principle operate through processes occurring both before and during/after copulations and being male or female driven. Prior to copulation, these are typically seen as male-male competition of access to females as mating partners and female choice of mating partners. When females mate with multiple males (i.e., are polyandrous), these processes can continue during or after copulations as sperm competition and cryptic female choice, respectively. The latter is a female postcopulatory mate choice where females bias

fertilization in favor of certain males, based on the phenotype of the male or his sperm (Eberhard 1996). The term is called “cryptic” because this form of female choice can be hard to observe, for example, in internal fertilizing species. Cryptic female choice is the part of sexual selection that to date is the least studied and is likely a consequence of this.

The research field cryptic female choice originated during the early 1990s, and the book that convincingly established cryptic female choice as an important component of sexual selection is the seminal book *Female Control: Sexual Selection by Cryptic Female Choice* (Eberhard 1996). With the development of techniques, the number of studies investigating and demonstrating cryptic female choice is increasing (but see below, [Defining and Demonstrating Cryptic Female Choice](#)). Females from all studied taxa have now been shown to be able to affect the outcome of a copulation and also to bias paternity, and in some cases the stage in the reproductive event in which this occurs is demonstrated.

Defining and Demonstrating Cryptic Female Choice

The definition of cryptic female choice diverges some, ranging from being general, such as “a female choice occurring during or after mating” (Thornhill 1983), to being very broad, such as “a female controlled process or structure that selectively favors paternity by conspecific males with a particular trait over that of others that lack the trait when females has copulated with both types of males” (Eberhard 1996) or be more specifically pinned down to be a mate choice carried out by a female, occurring at a postcopulatory stage disentangled from pre-copulatory processes and male adaptations to sperm competition (Birkhead 1998, 2000). Then again, due to the complex interactions that can occur between the sexes during and after copulation and because male adaptations

to sperm competition can be hard to disentangle from cryptic female choice, both processes have been suggested to jointly be called postcopulatory sexual selection (Birkhead et al. 2009).

As a consequence of what definition is used, how commonly cryptic female choice is demonstrated will differ. Based on Eberhard’s very broad definition of cryptic female choice, numerous potential mechanisms can take place by which females can conduct postcopulatory choice. These are ranging from female behavior during copulation to female physiology and morphology and to varying investment in offspring. Based on this definition, Eberhard claims that there are numerous examples of cryptic female choice in the animal kingdom (Eberhard 1996).

There is no doubt that there is great scope for females to potentially be able to have control on the outcome of mating and bias fertilization. Nevertheless, when using a more narrow definition of cryptic female choice, including only postcopulatory processes that are demonstrated to be female driven while ruling out pre-copulatory processes and male-driven processes (Birkhead 1998, 2000), the examples of when researchers have been successfully able to demonstrate cryptic female choice are reduced. This is because there are many and often complex ways in which males and females can interact both before and during copulation, in addition to how ejaculates and females, and sperm and eggs, can interact (Birkhead et al. 2009). It can therefore be challenging to separate pre- from postcopulatory processes and to separate the interaction of male adaptations to sperm competition and female influences on fertilization. If using paternity to infer cryptic female choice, variation in differential embryo mortality separated from female-induced biases in paternity should also be demonstrated (Birkhead 1998). This again highlights that separating cryptic female choice from other processes can be difficult, which in turn makes the study of cryptic female choice hard.

Mechanisms Used to Bias Sperm Use by Females

Independent of the applied definition of cryptic female choice, there are in principle four stages through which females have the potential to bias paternity: before, during, and after copulation (but before fertilization), or following fertilization (Birkhead and Møller 1998), and many stages in the female reproductive tract where biases can in principle occur (Birkhead and Brillard 2007). A cryptic female choice can thus in principle be explained in a range of behavioral, physiological, chemical, morphological, and genetic processes through which females can potentially bias paternity. For example, females can have control of oviposition and by biasing speed of oviposition, for example, to occur directly after a mating or delay it until she has remated can affect the paternity of the offspring. There is often a lot of variation in female reproductive tract morphology which in turn can explain a bias in paternity of offspring produced by these females. How actively females can use this in their favor is however less clear. Females of species as different as rodents, squid, and insects have been demonstrated to actively remove spermatophores, copulatory plugs, or ejaculates after copulation has occurred. Similarly, female differential ejaculate ejection (or sperm ejection) is observed in some mammals and birds (Birkhead and Pizzari 2002), while female sperm dumping is demonstrated in fruit flies (*Drosophila melanogaster*). Even if accepting an ejaculate, females may potentially have the ability to bias the transport of sperm to and from sperm storage organs in a manner that can affect female sperm use and bias paternity. Such biases have been demonstrated in insects to be explained by genetic relatedness between the male and female. In fishes, the ovarian fluid around eggs can affect sperm in ways biasing paternity, for example, by increasing sperm velocity of certain males. Sperm-egg interactions directly can also affect fertilization success, explained by genetic compatibility among the gametes. In external fertilizers, in other words

species where sperm and eggs are released into the water and fertilization is not occurring internally, cryptic female choice through gamete interaction can be the only way females may be able to affect fertilization. Finally, cryptic female choice can in principle also occur through a post-insemination pre-fertilization female bias meaning that the female may in some cases be able to perform a choice also occurs after insemination, before the pronuclei of males and females have fused (Carré and Sardet 1984, in Birkhead and Pizzari 2002). Although examples so far are from the animal kingdom, cryptic female choice can also occur in plants through similar processes as observed in animals, for example, gamete incompatibility and selection at the gamete level.

Conclusion

Females being able to bias fertilization through processes occurring during or after copulation enables females to increase control of paternity. There is a broad range of ways through which females may do this, ranging from behavioral to genetic interactions between individuals or gametes. Nevertheless, this cryptic female choice is often very hard to disentangle from processes occurring prior to mating, or that are male driven. As a consequence, studies clearly demonstrating this likely important and potentially widespread female mate choice are still relatively rare.

Synonyms

Paternal uncertainty

Definition

The likelihood that a male is unknowingly investing in a child that he did not father.

Introduction

One of the most recent and by far most comprehensive attempts to examine the risk of being cuckolded among human males was undertaken by Anderson (2006) based on a meta-analysis of the world's literature on paternity testing comprising over 75 articles. The incidence of nonpaternity rates from paternity testing laboratories ranged from 14.3 % to 55.6 %. The problem of course is that men do not petition for paternity testing out of idle curiosity. So Anderson

partitioned the incidence of nonpaternity into males with high paternity confidence (i.e., males who had no reason to question their paternity) and those with low paternity confidence. Among those with high paternity confidence the incidence of nonpaternity was approximately 2 %, or one out of fifty. However, for those who had reason to question their paternity (men with low paternity confidence), the incidence of nonpaternity was 30 %.

Paternal Uncertainty

While the incidence of nonpaternity varies as a function of paternity confidence, Anderson argued that nonetheless the incidence of paternity remains higher than the incidence of nonpaternity under most circumstances. However, it is important to realize that the risk of nonpaternity (i.e., being cuckolded) among males with low paternity confidence was a staggering 15 times higher than those with high paternity confidence. Thus there would appear to be some pretty sophisticated evolved mechanisms operating that function to inform males about nonpaternity, i.e., males who harbor questions about paternity are far more likely to have been cuckolded.

The other way to think about these dramatic differences in nonpaternity as a function of paternity confidence is that nonpaternity is a proxy for female infidelity. Because the likelihood of conception as a consequence of a single random sexual encounter is low (some estimates put it at one in a hundred) it means that the incidence of nonpaternity is the mere tip of the iceberg when it comes to the underlying incidence of female infidelity. Women do not get pregnant every time they engage in infidelity. In fact, the majority of cases of nonpaternity are probably a by-product of one or more established, long-term extra pair liaisons between a woman in a committed relationship and one or more extra pair males.

Anderson's sample included data on the incidence of nonpaternity all over the world, and since he found that the incidence of nonpaternity did not vary as a function of geography, culture, or ethnic group status it seems reasonable to conclude that nonpaternity and

female infidelity are cross-cultural universals. Moreover, there are reasons to believe that these estimates of nonpaternity are relatively conservative since effective contraception was not an option during most of human evolutionary history.

Conclusion

Indeed, since the data Anderson used included cultures that have liberal attitudes concerning human sexual behavior along with those that are much more restrictive and conservative, it suggests that being "sexually liberated" affects what people say – but not what they in fact do.

Cues of Female Estrous

Benedict Jones and Amanda Hahn
Institute of Neuroscience and Psychology,
University of Glasgow, Glasgow, UK

Unlike some other female primates, women do not display obvious sexual swellings during the high-fertility phase of their ovulatory cycles. This simple observation has led some researchers to assume that women's ovulatory status is completely concealed (Gangestad and Thornhill 2008). By contrast with this assumption, however, several lines of recent research suggest that women do display detectable cues of their ovulatory status, albeit ones that are considerably more subtle than those observed in some other primates.

For example, studies have presented evidence that women's clothing choices can act as a cue to their ovulatory status (Durante et al. 2008; Haselton et al. 2007). Women tend to display more bare skin and wear clothing judged by others as an attempt to look more attractive during the high-fertility phase of the menstrual cycle than they do during low-fertility phases (Durante et al. 2008; Haselton et al. 2007). Relatedly, women are more likely to wear red clothing (a color thought to increase women's sexual attractiveness, Elliot and Maier 2014) during the high-fertility phase of the menstrual cycle than during low-fertility phases (Beall and Tracy 2013; Eisenbruch et al. 2015). Although these results suggest that women's clothing can act as a cue to their ovulatory status, these findings have not replicated consistently in subsequent studies, suggesting they are not necessarily robust (Arslan et al. *in press*; Blake et al., 2017).

Further evidence that women display detectable cues to their ovulatory status has come from studies reporting that women's facial attractiveness increases during the high-fertility phase of the menstrual cycle (Roberts et al. 2004; Puts et al.

2013). These changes in facial attractiveness are not simply a consequence of changes in makeup use or hairstyle (Roberts et al. 2004) and do not appear to be due to changes in either skin coloration (Jones et al. 2015) or posture (Sulikowski et al. 2015). Similar fertility-linked changes in women's vocal (Puts et al. 2013) and body-odor (Gildersleeve et al. 2012) attractiveness have also been reported. Studies have also found that fertility-linked changes in women's body-odor attractiveness are sufficient to trigger changes in men's reported sexual desire and testosterone levels (Mondragón-Ceballos et al. 2013). However, the specific physical characteristics that underpin changes in women's facial, vocal, and body-odor attractiveness during the ovulatory cycle are currently not known.

The studies described above focused on identifying links between women's ovulatory status and specific aspects of their appearance. However, other studies have sought to demonstrate that women display cues to their ovulatory status by investigating changes in men's attitudes to their romantic partners across their ovulatory cycles. For example, women report that their partners engage in more mate-guarding behavior during the ovulatory phase of their menstrual cycle (Haselton and Gangestad 2006). Men also appear to become more attuned to physical cues in potential rivals, such as dominance, that women are thought to value more during the ovulatory phase than at other times (Fales et al. 2014). Findings such as these present converging evidence for the existence of detectable cues of women's ovulatory status.

Although evidence that women display subtle cues to their ovulatory status is accumulating, several important issues remain unresolved. For example, it is unclear whether fertility-linked changes in women's behavior and appearance are signals that evolved specifically to advertise their ovulatory status or are simply either imperfectly concealed cues (Haselton and Gildersleeve 2011) or a by-product of mechanisms that primarily signal between-women differences in hormone levels or fertility (Havlíček et al. 2015).

Definition

Cues that signal one's engagement in a romantic/emotional and/or sexual relationship with someone external to the primary relationship.

Introduction

Infidelity is typically defined as an act that breaks the agreement of monogamy between two individuals who are dating, married, or in a committed relationship (e.g., Hertlein et al. 2009). Infidelity may be emotional and/or sexual in nature and entail involvement with someone outside of the primary relationship, such that there is a breaching of a subjective contract that the couple created (Fish et al. 2012). People engaging in infidelity typically define it themselves as "cheating" on their partner (Walters and Burger 2013).

Infidelity is a well-studied topic within the psychology literature. This attention is not surprising given that it may have harmful consequences for all parties (Altgelt et al. 2018). It is linked to declines in psychological health, increased probability of transmission of sexually transmitted infections and disease, and increased physical abuse, homicide, and suicides (see Jackman 2015). Betzig (1989) reports that it is the leading reason for relationship dissolution in 160 cultures around the world.

Prevalence of Infidelity

The overwhelming majority of people in the United States largely disapprove of infidelity, such that Gallup Poll results indicate 90% consider it immoral while 65% state it is unforgiveable (see Fincham and Way 2017 for a review). However, despite disapproval, rates of infidelity remain high. Therapists who see clients about interpersonal relationship issues estimate that over half of their practice pertains to couples coping with infidelity (Hertlein et al. 2009).

Actual prevalence rates vary dramatically across samples, partly in response to the

population examined, the methods used, and how infidelity is defined. For example, Walters and Burger (2013) review how researchers have labelled infidelity as extramarital involvement, extramarital relationships, extradyadic relationship, extradyadic activity, relationship infidelity, relational transgressions, and extramarital sex. In terms of prevalence, Wiederman and Hurd (1999) report 75% of men and 68% of women say they have engaged in extradyadic relational behavior, such as kissing or sexual intercourse. Mark et al. (2011) found 23.2% of men and 19.2% of women in heterosexual unions stated they had committed sexual infidelity in their current relationship. A far lower rate was found by Fincham and Way (2017), where between 2% and 4% of spouses reported having sex with a secondary partner in the past 12 months, with minimal sex differences in infidelity. Rates of infidelity may be far higher among dating than married individuals (see Jackman 2015). Generally, married individuals report lower rates of infidelity than those who are co-habiting or dating (Adamopoulou 2013). There also seems to be fluctuation due to seasonality: Infidelity peaks during the summer in the United States, which has been theorized to relate to increased travel to a different geographic area, leading to lower probability of the infidelity being detected by a partner (Adamopoulou 2013).

Linking Infidelity with Parental Investment Theory

Infidelity may be viewed from the perspective of lost investment, in that it signals the lack of a partner's commitment to the current relationship (Rusbult 1980). The lost investment can be best understood in light of parental investment theory, with an infidelity being considered primarily sexual or emotional in nature (e.g., Buss and Schmitt 1993). According to parental investment theory, it may be argued that men benefit most from establishing sexual contact with many fecund women. Men have a much smaller obligate parental role in children's lives than women, and therefore, it is thought that they should maximize their number of reproductive

partners and attempt to increase the number of children they sire. Thus, it may be most adaptive for men to have sexual relations with numerous women, including those outside of their committed relationship. However, simultaneously, men are presumed to be especially sensitive to a partner's sexual fidelity. Men are separate from the birth act (i.e., they do not give birth) and thus must rely on second-hand information to determine whether children are genetically related to them. They typically value sexual loyalty in their partners and attempt to avoid misallocated investments of time, resources, and energy into children of interlopers, especially when misplaced investments could harm their abilities to successfully invest in their own genetically related children. Consequently, men are thought to be more distressed by the thought of a partner having a sexual, as opposed to emotional, infidelity (Buss et al. 1992).

Contrariwise, women's obligate investment in parenting is far higher than men's, and consequently, they are argued to be most concerned with finding high-quality mates. Women have been considered reliant to varying degrees on men's resources, particularly when pregnant. Further, men's help with children and potential protection of their children (and the mother) is advantageous. Thus, women are thought to be particularly sensitive to a mate's emotional commitment and would be more distressed by it than sexual infidelity (Buss et al. 1992). Further, women have been reported to be more prone to emotional infidelity (i.e., falling in love or forming an emotional attachment to someone outside of their relationship) than sexual infidelity (Blow and Harnett 2005).

Motives for Engaging in Infidelity

There are various motives for engaging in an infidelity. Glass and Wright (1992) propose four main categories: sexual, emotional, love, and extrinsic (e.g., revenge, career advancement). They detailed that men report more sexual motives than women, while women report more

emotional motives than men. However, they found no sex differences for emotional or extrinsic motivations. Expanding on this idea, Omarzu et al. (2012) asked 22 men and 55 women currently engaged in an infidelity about their reasons for initiating such an arrangement and their perception of the emotional consequences of the infidelity. They largely replicated the earlier findings of Glass and Wright, in that they discovered motivations related to sex, emotional intimacy, love, revenge, and curiosity/excitement. Further, they documented that dissatisfaction with the primary partner (and relationship) was central to sexual, emotional, and love motivations, as was the opportunity for finding additional satisfaction. Both sexes were equivalent in saying that their infidelities were driven by sexual or emotional dissatisfaction with their primary partner. Men, though, were more likely to state they have accepted an opportunity to have more sex, while women were more likely to say they had accepted opportunity to find an emotional connection. Men, alone, said they engaged in infidelity due to sexually based curiosity or excitement.

Cues of Infidelity: Intentions

Detecting cues of potential infidelity is an important research topic for many reasons. At face value, it is informative to examine how individuals perceive subtle signals of other's behavior or intention. However, the detection of cues signaling infidelity may elicit emotions and behavior, specifically jealousy, in a partner. A man's experience of sexual jealousy, in particular, may be harmful toward a woman, as it is the most frequent cause of domestic battery and spousal homicide (Buss and Shackelford 1997). Therefore, detection of cues is a significant area of interest.

To start, infidelity may be detected via one's intentions. One could also examine intentions to commit infidelity. Actual behaviors have been linked to intentions to commit the behavior, which are in turn grounded by one's attitudes toward the behavior and subjective norms (e.g.,

the views or behaviors of those in one's social circles). Jackman (2015), in a study of 347 women and 165 men, found the most significant correlate of infidelity intentions were positive attitudes toward infidelity, which is influenced such that men, those low in religiosity, and individuals who have committed infidelity in the past are more likely to view it positively. Further, those with high self-efficacy and who have a social network that supports their infidelity is important.

Cues of Infidelity: Sexual Excitement and Performance Anxiety

A source of cues is revealed by work on the relational factors that may predict infidelity. Mark et al. (2011) studied predictors of sexual infidelity in 506 men and 412 women who were currently in heterosexual monogamous relationships. They found men's higher propensity toward sexual excitement, higher sexual performance anxiety, and an increased tendency to engage in sexual behaviors they may regret during times of negative affect all predicted sexual infidelity. The authors suggest that concern regarding sexual performance failure may be due to seeking high-risk situations to ensure arousal. It could also be due to participants believing that if their sexual performance is poor, there is no obligation to see the extradyadic partner again, and hence, they are protected from embarrassment or humiliation. For women, infidelity was predicted by higher sexual performance anxiety, but also low levels of happiness within the relationship, and low compatibility with their primary partner regarding sexual attitudes and values. The authors concluded that personality characteristics related to sexuality and for women, relationship features, are more important than other demographic variables such as relationship status, education, income, or religiosity. Returning to the topic of cues, identifying one's level of sexual performance anxiety, compatibility of sexual attitudes and values, and happiness within the relationship may be informative.

Cues of Infidelity: Personality

Cues of infidelity may also take the form of personality traits, in that one may predict the likelihood of a partner being involved in an infidelity based on whether they exhibit certain traits. For example, extraversion is linked to sensation seeking, seeking novelty, and sociability; it is also thought to be linked to finding sex more rewarding and seeking more mating opportunities, even if such activities entail high levels of risk. High extroversion has been associated with a higher propensity toward infidelity in a study of 545 British adults (Nettle 2005). Participants varied from those who had been loyal to their partner through to those with multiple occurrences of infidelity, and as extraversion increased in participants, so too did reported levels of infidelity. While this finding is accurate for both sexes, the effect size was larger and significant only for men, not women.

Further, in a large cross-cultural study of 52 nations in 10 world regions, low agreeableness and low conscientiousness were significantly related to infidelity for both men and women (Schmitt 2004). Individuals who describe themselves as being involved in an infidelity generally possess personality traits that are linked to a lack of trust, low empathy, a tendency to be disorganized, and are unreliable.

Individuals with high neuroticism, indicating emotional instability and high levels of worry, reported higher rates of infidelity in past and current relationships, an effect that appears to be stronger among women than men (see Altgelt et al. 2018 for a review). However, these connections between personality traits and infidelity are far from simple, and indeed the traits of the partner in the relationship also warrants attention. In their study of 108 newlywed couples over a 3-year timespan, Altgelt et al. (2018) documented that spouses with partners high in neuroticism or extraversion were more likely to engage in infidelity, and husbands with partners high in narcissism (i.e., feelings of superiority and low empathy) were more likely to engage in infidelity.

Cues of Infidelity: Attachment

Adult attachment may also matter; Attachment anxiety and avoidance significantly correlates with infidelity (Fish et al. 2012). Anxiety here refers to one's strong desire to receive positive attention from a partner, coupled with a fear that the partner or romantic relationship will fail to meet one's needs. Avoidance, alternatively, is one's difficulty in finding comfort in psychological intimacy or emotional connections and the need to maintain independence within one's romantic relationships. Therefore, one's attachment style may serve as a cue about their propensity to engage in infidelity.

Cues of Infidelity: Actual Behaviors

Shackelford and Buss (1997) sought to identify the behavioral cues that signal a partner's sexual and emotional infidelity. They performed two studies of college students. In the first study, participants nominated behaviors that may cause them to suspect a long-term partner was engaging in sexual or emotional infidelity. Thirty students of each sex were primed to think about a past, current, or future partner in a committed romantic relationship and imagine that partner was having sex with someone else or falling in love with someone else. Then, participants listed 10 cues that would lead them to suspect sexual or emotional infidelity, with cues being specific actions a partner may do, physical cues, sexual cues, emotional cues, behavioral cues, or verbal cues.

The results indicated that men and women overlapped considerably in the cues they provided for the two forms of infidelity, resulting in 170 distinct cues. Examples of the cues were: acting unusually angry when with their partner, being unusually critical of their partner, avoiding the topic of sex with their partner, spending less time on their appearance before seeing their partner, being bored with their partner sexually, breaking up with their partner, acting overly affectionate to their partner, avoiding dates with their partner, and avoiding a certain person as a topic of conversation with their partner.

In the second study, 114 men and 116 women examined the nominated behaviors from study 1 and then rated each act on how diagnostic it was for indicating sexual and emotional infidelity. Half the participants rated the likelihood that infidelity occurred based on the cues, while the remaining half rated the likelihood that the cue would be performed, given an infidelity occurred.

The 170 cues from the first study were grouped, using a factor analysis of ratings, to reveal 14 factors. These factors are as follows.

1. Angry, critical, argumentative toward partner. Here the person who has engaged in an infidelity is uncharacteristically angry or critical of the primary partner, less forgiving of the partner's mistakes, or seems to be seeking reasons to start arguments with the partner.
2. Apathetic toward partner. Cues for this factor are a general loss of interest in the primary partner, including less excitement about seeing the partner, not disclosing feelings to the partner, and claiming to be too tired to engage in sexual activity with the partner.
3. Relationship dissatisfaction and loss of love toward partner. This factor includes suggesting seeing other people external to the relationship with the primary partner, talking about ending the relationship with the partner, and reporting to have fallen out of love.
4. Passive rejection of partner and inconsiderateness. Here passive rejection of the primary partner occurs. Other behaviors are not saying "I love you" to the partner and failing to state any time spent together is enjoyed. Acting rudely toward the partner and being less gentle during sex is also included.
5. Reluctance to discuss a certain other person. Cues for this factor revolve around avoidance. The person who has engaged in the infidelity avoids talking about a particular other person or appears nervous if that person's name is raised in conversation with the primary partner.
6. Reluctance to spend time with partner. This factor includes cues where one avoids spending time with the primary partner, whether it be alone or together as a couple with family or friends.

7. Increased reference to, and time spent with, another person. Cues range from the person who engaged in the infidelity spending more time with another person, wearing an item of clothing belonging to another person which is noticed by the primary partner, calling the partner an incorrect name, or telling the partner about a desire to have sex with another person.
8. Acting guilty or anxious toward partner. The person who engaged in the infidelity is uncomfortable, nervous, or seems guilty when in close proximity to the primary partner.
9. Emotional disengagement from partner. Here the cues include forgetting the couple's anniversary or important dates, not making declaration of love to the primary partner, and providing minimal response to the partner's declaration of love.
14. Physical signs of sexual infidelity and disinterest in sexual exclusivity. Some cues include the recent contraction of a sexually transmitted infection or disease by the person engaged in infidelity or smelling like sex despite no sexual activity with the primary partner. This factor also includes the person committing infidelity stating they do not want to be sexually exclusive to the partner.

The remaining five factors directly contain cues regarding sexual behavior. They are as follows.

10. Sexual infidelity is revealed. The primary partner directly witnesses a sexual act between the person who engaged in the infidelity and another person, or the sexual infidelity is stated openly.
11. Changes in normal routine and sexual behavior with partner. Cues include changes in sleeping patterns or eating habits of the person who engaged in the infidelity. The person also tries new sexual positions with the primary partner or exhibits less orgasms during sex with the partner.
12. Increased sexual interest and exaggerated display of affection toward partner. Here there is a display of increased interest in sexual behavior with the primary partner, saying "I love you" more often than usual, and greater than normal displays of affection.
13. Sexual disinterest and boredom with partner. This factor includes cues such as boredom during sex with the primary partner, behaving mechanically during sex with the partner, or an inability to become or remain sexually aroused when with the partner.

Twelve of the 14 factors were found to be diagnostic of one form of infidelity relative to the other. There were the five factors listed for sexual infidelity. Being apathetic toward the partner (item 2 in the preceding list) and increased reference to, and time spent with, another person (item 7) did not differentiate between sexual or emotional infidelity. The remaining items were diagnostic of emotional infidelity.

Further, in the second study, Shackelford and Buss (1997) reported that the sex of the person doing the ratings and the sex of the person engaged in the infidelity mattered. Men and women rated performance of the cues within the factors as more diagnostic of infidelity when the person engaged in the infidelity was a member of the opposite sex. The authors concluded that people seem primed to infer infidelity more easily when it is an opposite-sex person who is displaying the cues as compared to a same-sex person. That is, men are more sensitive to cues of infidelity when they are displayed by a woman, and women are more sensitive to cues of infidelity when displayed by a man.

The cues for sexual infidelity incorporate a wide assortment of behaviors, ranging from obvious and overt signals such as revealing the infidelity, or physical signs of infidelity, to those that are subtler and covert, including changes in normal routines or increased sexual interest and exaggerated displays of affection. The weakest cue was sexual disinterest and boredom with the partner. Thus, the diagnostic value of the cues also varies accordingly, such that those that are more covert were rated as less diagnostic than those that were obvious.

Moreover, the authors posited that cues underlying emotional infidelity are not as clear-cut

as sexual infidelity due to the fact that it is a less identifiable form of infidelity. Emotional infidelity is less physically focused and instead pertains to the diversion of money, attention, support, or love and is typically accompanied with a reduction of time invested in the primary relationship.

Overall, women provided higher diagnostic ratings for the cues than men when the sex of the person committing the infidelity was not considered. The researchers contended that women tend to be more attuned to relationship dynamics than men, and given men are more likely to be involved in infidelity than women, it is possible that women have evolved a greater sensitivity to cues signaling potential infidelity.

Schützwohl (2005) extended these findings by examining the threshold at which participants reported feeling the first pangs of jealousy and then when the jealousy became unbearable. The cues were adapted from Shackelford and Buss (1997), such that they were listed in ascending order of diagnostic rank. A student sample of 95 men and 101 women completed the study. He found that the threshold for the first pangs of jealousy did not vary significantly by sex for emotional or sexual infidelity, as determined by the number of cues. However, after jealousy was experienced, men required fewer cues for sexual infidelity than women, and women required fewer cues for emotional infidelity than men, to reach the threshold where the jealousy felt unbearable. These results were replicated when reaction time was considered, instead of simply the number of cues.

Cues of Infidelity: Future Directions

Future work on cues of infidelity may include readily identifiable features that serve as accurate predictors of past infidelity behavior. Recently, Hughes and Harrison (2017) examined voice as a potential cue of infidelity. In their study, they used 10 voices of men and 10 of women, with half of the speakers self-identifying as having engaged in an infidelity at some point in their lives. Based on a brief recording (controlled for voice attractiveness, pitch), a student sample of 64 men and

88 women correctly identified those who had been involved in infidelity, signifying voice may contain signature cues of past infidelity behavior.

Future work may also incorporate social media. Cues of infidelity may occur on platforms such as *Snapchat*, where individuals receive messages from other users. Dunn and Ward (2019) reported that men imagined greater distress about a partner receiving a sexual *Snapchat* message revealing an infidelity than one revealing an emotional infidelity. The reverse trend was apparent for women. Therefore, the role of social media in infidelity, and in particular how it may provide cues as to potential or current infidelity, may be worth exploring.

Conclusion

Infidelity occurs within monogamous relationships where there is a social contract of exclusivity. It is related negatively to health and relationship outcomes, and is globally the main reason for relationship dissolution. Detecting a partner's infidelity, whether it be sexual or emotional in nature, presumably has strong evolutionary roots, given that misallocated time, energy, and resources may impact negatively on one's individual fitness. There are numerous cues of infidelity, with more research on how people detect sexual than emotional infidelity. Cues of infidelity may relate to personality traits, patterns of attachment, or actual

behaviors. Future work may examine the role of social media in providing cues or how some cues provide immediate, accurate information about past infidelity behavior.

[Descriptive relativism](#); [Metaethical relativism](#); [Normative relativism](#)

Definition

Moral relativism refers to three distinct but related philosophical positions (Brandt 2001, pp. 25–28). *Descriptive relativism* is the hypothesis that there are pervasive and irresolvable moral disagreements between individuals or cultures. *Metaethical relativism* holds that moral claims can only be evaluated as true or false relative to a particular individual or culture's moral standards. Metaethical relativism thus denies that there are objective standards of moral truth that are universally applicable to all people and societies. *Normative relativism* is the prescriptive position that we should tolerate individuals or cultures with different moral standards. Such tolerance prohibits people from judging or imposing their moral standards on people or cultures with different moral standards. Each form of relativism can be cast at the individual level, i.e., that there are fundamental disagreements in individual moral standards, that moral truth must be evaluated relative to the standards of different individuals, and that we must tolerate individuals with different moral standards. *Cultural relativism* may refer to any of these forms of relativism cast as differences between cultures rather than individuals. (*Cultural relativism* may refer to other forms of relativism unrelated to morality, such as methodological and epistemic/cognitive relativism. Methodological relativism is the practice of suppressing enculturated biases when studying other cultures (Obeyesekere 1966). Epistemic relativism holds that different cultures or individuals employ radically different conceptions of knowledge, justification, or

reasoning (Boghossian 2006; Rorty 1991). Only moral forms of cultural relativism are discussed here (but see Brown 2008; Meiland and Krausz 1982).)

Introduction

This entry will not focus on the history of moral relativism or offer extensive discussion of arguments for and against relativism. Instead, it will provide an overview of each form of relativism and discuss their relationship with evolutionary psychology. (For more historical treatments of moral and cultural relativism, see Brown (2008) and Hollinger (2003, pp. 708–721).) Evolutionary psychology has important implications for all three forms of relativism. The extent to which moral judgment is constrained by evolved psychology plays a critical role in the possibility of deep and pervasive moral differences and could serve to circumscribe, falsify, or support some version of descriptive relativism. Evolutionary psychology is also relevant to metaethical and normative relativism. In part, this is because the practical significance of normative and metaethical relativism depends on the moral diversity postulated by descriptive relativism. However, philosophers also appeal to evolutionary influences on human psychology to support (Collier and Stingl 1993, 2013 Harman 2000; James 2009; Sterelny and Fraser 2016; Zamulinski 2007) or cast doubt on moral realism. Arguments in favor of moral realism are relevant to normative relativism insofar as the moral facts they purport to establish conflict with interpersonal and intercultural tolerance and may conflict with metaethical relativism if they purport to establish objective moral facts. Arguments against moral realism, on the other hand, are relevant to metaethical relativism insofar as they cast doubt on objectivist moral theories. The most prominent evolutionary arguments against moral realism are *evolutionary debunking arguments (EDAs)*. These arguments appeal to the evolutionary origins of moral judgment to undermine justification for moral beliefs (Kahane 2011). EDAs have become increasingly popular in the philosophical

literature and have spawned a growing debate over the relevance of evolutionary theory to metaethics. Evolutionary debunking arguments have received considerable support (Cline 2015; Fraser 2014; Griffiths and Wilkins 2010; Joyce 2006, 2013, 2016b; Lillehammer 2003; Mason 2010; Millhouse et al. 2016; Mogensen 2014b; Street 2006, 2008; Wright et al. 2014) but have also attracted many critics (Behrends 2013; Berker 2014; Bogardus 2016; Brosnan 2011; Carruthers and James 2008; Deem 2016; Enoch 2010; FitzPatrick 2014a, b, 2015; Kahane 2011; Mogensen 2014a; Peters 2012; Schafer 2010; Shafer-Landau 2012; Skarsaune 2011; Talbott 2015; Toner 2011; Vavova 2014; Wielenberg 2010). Even if these arguments fail on philosophical grounds, they all depend on specific claims about the evolution of moral cognition. Finally, while it is unlikely that evolutionary psychology could play any direct role in determining whether or not we ought to tolerate people or cultures with different moral values, it may inform normative relativism by providing practical insight into how to devise institutions, policies, and norms that facilitate tolerance.

Moral Relativism

Descriptive Relativism

Descriptive relativism is the empirical hypothesis that there are pervasive and fundamental moral disagreements between individuals (*descriptive individual relativism*) or cultures (*descriptive cultural relativism*). The most common source of evidence in support of descriptive cultural relativism is the prevalence of practices that are permissible or even obligatory in one culture, but prohibited in another, such as female genital mutilation, polygamy, cannibalism, and human and animal sacrifice. Analogous support for descriptive individual relativism draws on the existence of moral variation within a population. In either case, variation in moral belief is uncontroversial, so it may seem that descriptive relativism consists in the trivial claim that people often hold conflicting moral views. This is not the case. Descriptive relativism is committed to the

existence of *fundamental moral disagreements* or moral disagreements that cannot be resolved in principle because they express differences in basic moral beliefs and commitments (Moody-Adams 2009).

Many moral disagreements are not fundamental but are instead disputes over nonmoral facts or the result of misunderstandings or errors in reasoning. Two people with the same moral standards may hold conflicting views about gun control because they disagree about whether it reduces crime. Once both individuals were in full possession of the facts and knew whether gun control reduced crime, the disagreement would in principle dissolve. Errors in reasoning could also lead two people to disagree (or at least think they disagree) about a moral issue. Rational discussion could lead either side of a dispute to identify errors or inconsistencies in their position, modify their beliefs, and come to an agreement. If so, this dispute would involve misunderstandings that could in principle be corrected, not a fundamental moral disagreement.

Since it is possible that most or even all moral disagreements would dissolve once both sides of a dispute were in possession of the facts and were reasoning correctly, descriptive relativism must demonstrate that there would still be many moral disagreements even under such optimal conditions. In spite of this difficulty, empirical findings could vindicate descriptive relativism by providing compelling evidence that cultures or individuals really do have fundamentally different moral values.

Metaethical Relativism

Metaethical relativism is the philosophical position that moral claims are only true or false relative to an individual or group's moral standards. (There are other possibilities. Harman (1975) and Harman and Thomson (1996) argue that moral claims could be relativized to the shared context of the agent making a moral claim along with their intended audience (Joyce 2015). Moral claims could also be relativized to groups other than cultures, such as superordinate cultural groups (e.g. "the West") or different species.) Metaethical relativism does not deny

that there are moral facts; it only denies *metaethical objectivism*, the view that there are objective moral facts that are universally applicable to all individuals and cultures. Unlike metaethical objectivism, metaethical relativism allows the same moral claim, e.g., “slavery is wrong,” to be true relative to one moral standard but false relative to another.

It may seem absurd to suggest that the same claim can be both true and false, but ordinary language already incorporates linguistic features that permit expressions to have variable truth values. This is achieved by employing *indexicals*, linguistic expressions or behaviors (e.g., pointing) that allow statements to vary in meaning from one context to another or from one speaker to another. Common indexicals include “I,” “you,” “he,” “she,” “here,” “there,” “yesterday,” and “today” (Kaplan 1989). For example, if Alex says “I am at home,” she is referring to herself and her home, but if Sam says “I am at home,” she is referring to herself and her home, not Alex or Alex’s home. Indexicals also permit the truth of a claim to vary. If Alex is facing north and Sam is facing south, the statement “I am facing north” is true if Alex says it but false if Sam says it.

Metaethical relativism incorporates a similar indexical component into moral claims, such that each moral claim includes an implicit reference to a particular moral framework (Joyce 2015; but some object to this characterization, see Harman 2015). Since different people and cultures have different moral standards, the truth of a moral claim will depend on which moral framework is referenced. For example, Alex may live in a culture that prohibits slavery, while Sam lives in a culture that permits it. According to cultural metaethical relativism, when Alex says, “Slavery is wrong,” she implicitly refers to her culture’s standards. Since slavery is wrong in Alex’s culture, this statement is true. When Sam says “Slavery is wrong,” she references her culture’s standards. Since slavery is permissible in Sam’s culture, this statement is false. Thus, the same moral claim, “Slavery is wrong,” can be true when one person says it but false when another says it, because each claim implicitly refers to a different moral framework.

Although metaethical relativism treats moral claims as being true or false, critics often conflate it with moral skepticism (the belief that moral claims are unjustified or their truth is unknowable) or outright rejection of moral truth or warn that it inevitably leads to an egoistic or nihilistic view of morality (Wong 1998). For example, Pope Benedict XVI warned that “[W]hen policies do not presume or promote objective values, the resulting moral relativism . . . tends instead to produce frustration, despair, selfishness and a disregard for the life and liberty of others” (Ratzinger 2005). Pope Benedict may or may not be correct to worry that denying objective right or wrong has negative behavioral consequences, but a relativistic view of moral truth does not itself consist in a rejection of moral truth (unless moral truth is question-beggingly defined in such a way as to exclude relative truth) nor does it logically entail any normative implications, including the advisability of wanton indulgence. Furthermore, although metaethical relativism does deny that there are objective moral truths (at least in its most radical form), the denial of objective moral truth does not entail that the world is “without value,” unless the only legitimate values are objective, which would beg the question if it were offered as a criticism of metaethical relativism.

Admittedly, Pope Benedict does not necessarily intend to critique sophisticated philosophical positions that are careful to disentangle different forms of relativism, and he might concede that metaethical relativism, construed strictly as a metaethical and not a normative stance, is not subject to their concerns. Nonetheless, his remarks echo the common sentiment that there *is* a relationship between a denial of objective moral truth and the adoption of pernicious attitudes and behavioral dispositions (Kanarek 2013; Tasioulas 1998). Since metaethical relativism does not logically entail normative consequences, it could at best have only a contingent relationship with egoism, nihilism, or any other normative or behavioral consequences. Such a relationship *may* exist, but it would require empirical evidence to establish it. Researchers are beginning to explore this relationship, and preliminary findings suggest that

concerns about the deleterious consequences of relativism may be at least somewhat justified. Rai and Holyoak (2013) found that priming participants with relativism increased dishonesty and cheating, while Young and Durwin (2013) found that priming objectivism led to substantial increases in donations to charity but priming relativism did not.

Critics of metaethical relativism also argue that, because it does not privilege any moral systems over others, it is incapable of providing rational justification for condemning the moral practices of other people and cultures, even when those practices include genocide, torture, or other atrocities (Bennett 2002, p. 46; Pojman 2004; Rachels 2001). Defenders of metaethical relativism could respond by insisting that it does not have any normative implications, but others have responded by abandoning an entirely relativist metaethics and instead propose objectivist constraints that limit which moral systems can be legitimate. This *moderate metaethical relativism* can be distinguished from *radical metaethical relativism*, which asserts that all moral truth is relative and that no moral claims are objectively true or false (Carson and Moser 2001). This radical form of metaethical relativism does entail, as critics maintain, that all moral frameworks are equally true and that none hold any privileged status over others. It is this radical stance that has attracted harsh criticism. But metaethical relativism need not entail that *all* moral claims are relative. It is possible to regard some moral practices as relative but others as objective. Copp (1995), Brandt (1984), Velleman (2013), Foot (2001, 2002), and Wong (1995, 2009) have all defended moderate views of this sort.

Wong (1995, 2009) for instance, defends what he calls “pluralistic relativism” (cf. Xiao and Huang 2014). According to this view, conflicting moral frameworks could each be true, but human nature and local circumstances place constraints on which moral frameworks are legitimate (Gowans 2015). These constraints are based on the finite set of moral frameworks that, for instance, promote human flourishing and facilitate cooperation within a society. Since there are multiple ways to meet these conditions, mutually

incompatible moral systems could be equally consistent with moral truth. Any moral system that fails to achieve these standards, on the other hand, is objectively false. Wong’s pluralistic relativism, and views like it, is neither fully relativist nor fully objectivist. To proponents of more “pure” conceptions of relativism, this may be too great a concession. Nonetheless, moderate metaethical relativism offers a compromise that circumvents some of the difficulties faced by more radical forms of relativism.

Normative Relativism

Normative relativism is the prescriptive position that we must tolerate the moral practices of different people and cultures. Normative relativism does not require people to support moral frameworks that differ from theirs, but it does prohibit them from imposing their values on other cultures or judging them according to their own moral standards. The obligation to tolerate other cultures may be framed not as a principle of acceptance but as a principle of noninterference (Bennigson 1999; Gowans 2015). Few philosophers defend the notion that descriptive or metaethical relativism necessarily entail normative relativism (see Harrison 1976; Wong 2009; Williams 1972). Instead, contemporary debate concerns whether there is an indirect relationship between descriptive/metaethical relativism and normative relativism, such that descriptive and metaethical relativism in some way provide a rationale or a context in which a norm of intercultural or interpersonal tolerance is more likely, more desirable, or more philosophically defensible (see Bennigson 1999; Graham 1996; Ivanhoe 2009; Kim and Wreen 2003; McKinnon 2007; Rachels 2001; Prinz 2007; Tilly 1998; and Wong 1984).

Nonetheless, it is illustrative to examine a formal argument that tolerance follows directly from moral relativism. Pojman (2004) attributes one such argument to Herskovits:

1. If moral claims are only true or false relative to a particular culture’s standards, then there are no nonrelative justifications for members of one’s culture to morally judge the standards of another culture.

2. If there are no nonrelative justifications for members of one culture to morally judge the standards of another culture, then we ought to tolerate cultures with different moral standards.
3. Moral claims are only true or false relative to a particular culture's standards.
4. We ought to tolerate cultures with different moral standards. (Adapted from Pojman 2004, pp. 244–245).

This argument would have no practical significance if descriptive relativism was false, but the falsehood of descriptive relativism would not demonstrate that any of the argument's premises were false. The argument relies only on the hypothetical possibility of cultures with different moral standards. Nonetheless, descriptive relativism asserts only that there are fundamental moral disagreements. If true, this fact by itself would have no normative implications.

In addition, this argument fails to show that tolerance follows from metaethical relativism. As Pojman (2004) points out, "If morality simply is relative to each culture, then if the culture does not have a principle of tolerance, its members have no obligation to be tolerant" (p. 245). More importantly, we could not infer from the fact that moral truths are true relative to a particular framework that there is a universal, nonrelative moral duty to tolerate people who subscribe to different frameworks, since the very existence of such nonrelative moral facts is precluded by metaethical relativism. Even if the normative relativist endorsed a hybrid metaethical theory in which the obligation to tolerate others was objectively true, such a position would not follow from metaethical relativism itself. This suggests that the difficulty with this argument is the second premise. Even if there were no nonrelative way to condemn the practices of other cultures, this would not in any way entail that it were *morally wrong* to condemn the practices of other cultures. A culture could even include among its standards an obligation to be intolerant toward other cultures. Nothing about metaethical relativism precludes this possibility or suggests that it is less preferable than tolerance. Pojman makes this

point himself, concluding that, "[F]rom a relativistic point of view there is no more reason to be tolerant than to be intolerant, and neither stance is objectively morally better than the other" (p. 245).

Although normative relativism does not follow deductively from descriptive or metaethical relativism, they may provide indirect support for tolerating people or cultures with different moral practices. This could be achieved via inductive arguments, though Kim and Wreen (2003) consider and reject several attempts, and ultimately conclude that there is no inductive link either. Even if we accept their conclusions, there may still be a psychological link between descriptive or metaethical relativism and normative relativism. The belief that metaethical relativism is true, and that because of this there are no objective standards of moral truth, could induce a state of reflection and critical self-examination that would lead us to be more cautious in morally condemning others. Westermarck (1932) suggests this possibility, stating that "Could it be brought home to people that there is no absolute standard in morality, they would perhaps be on the one hand more tolerant and on the other more critical in their judgments" (p. 59). Baghrmian (2015) argues that such transformative experiences may not even require the belief that moral standards are relative but could instead result from exposure to and reflection on the sheer diversity of moral views that exist. Citing Knobe and Nichols (2007), she adds that such experiences may result in a crisis of faith similar to those experienced by children who, growing up in insular religious communities, discover that others do not share their religious beliefs, since circumstances like these may reflect instance of "contingency anxiety," as discussed in Mogensen (2015):

... [T]he discovery of religious diversity can prompt the thought that it's in some sense accidental that one happens to be raised in a Christian household rather than a Hindu household. This kind of arbitrariness can make the child wonder whether there's any reason to think that his religious beliefs are more likely to be right than those of the Hindu child. (p. 11)

(Westermarck's and Baghrmian's proposals could be correct, but if so, they would entail

only an indirect and contingent capacity for metaethical and descriptive relativism to encourage tolerance. They would be indirect and contingent in that any tendency for people to move from metaethical or descriptive relativism to normative relativism would not result from a rational chain of inferences or the logical deduction that the latter is a corollary of the former but of some further set of facts about the interaction of accepting the metaethical or descriptive relativism with other characteristics of specifically human psychology).

Even so, the discovery of a contingent empirical connection between metaethical or descriptive relativism and an increased tolerance for different moral practices would be fascinating and important. Some researchers have already found evidence consistent with this possibility. Goodwin and Darley (2012) found that, compared with relative moral beliefs, objective moral beliefs were associated with reduced comfort with people who disagreed, the judgment that people who disagreed were more immoral, and reduced willingness to reconsider that belief. Wright et al. (2014) found that objective moral beliefs were associated with greater unwillingness to date, interact with, or help people who did not share the same belief than nonobjective moral beliefs. These studies suggest that relativism is associated with greater tolerance of moral diversity than objectivism, but the correlational nature of these findings does not provide causal evidence that a change from objectivism to relativism would lead to greater tolerance. If such a relationship results from protracted reflection and critical self-assessment, as Westermarck and Baghramian suggest, such evidence may be difficult to acquire, since it is doubtful that priming participants with evidence of moral diversity or presenting an argument for metaethical relativism would induce anything approximating serious reevaluation of one's moral beliefs, especially if participants are evaluated immediately or shortly after the manipulations. Future research should investigate the causal impact of changes in metaethical beliefs and evaluate a broader range of behavioral consequences. Such research could also attempt to more closely replicate the impact of more serious

reevaluation of moral beliefs over an extended period of time to more specifically test Westermarck's and Baghramian's suggestions. Since it is possible that increases in tolerance are a specific instance of a global reduction in moral concern, one possibility is that reflection on moral diversity or relative moral truth increases tolerance via a global reduction in moral concern.

Evolutionary Psychology and Moral Relativism

Evolutionary Psychology and Descriptive Relativism

Even on the most uncharitable assumption of widespread exaggeration and misinterpretation, there is little doubt anthropologists have accurately documented an extraordinary degree of moral diversity. And there is no question that political, religious, and personal divisions lead people with similar cultural backgrounds to differ, often fiercely, over moral issues. All this would suggest that the case for descriptive relativism is settled. Yet descriptive relativism cannot be demonstrated by merely pointing to differences in moral beliefs, because it is unclear from the existence of such disagreements whether they result from differences in nonmoral beliefs, failures in reasoning or reflection, or genuine differences in fundamental moral values.

Descriptive relativism may be an empirical hypothesis, but it is not a hypothesis that could be confirmed or disconfirmed exclusively by observational research. Descriptive relativism holds that *even if* people were fully informed and reasoning properly, they would still disagree about a wide range of moral issues. But people are far from fully informed, and the human mind is riddled with cognitive biases that hinder people's ability to rationally evaluate information even when it is available (Tversky and Kahneman 1974). Descriptive relativism, as an explanation of moral diversity, rests on a conjecture about what would happen in a highly idealized hypothetical state of affairs that has not, and likely never will, come to pass. This does not invalidate it as a legitimate empirical hypothesis. Sufficient

evidence could show that the best explanation of available data is that extensive moral disagreement would likely persist under ideal circumstances, but establishing this claim is far more difficult than is commonly appreciated.

Descriptive relativism must overcome several theoretical and empirical difficulties to establish itself as the best explanation of moral diversity. It is subject to conceptual, normative, and methodological difficulties that make it difficult to precisely state, operationalize, and empirically evaluate. These difficulties make observational research alone inadequate to demonstrate widespread fundamental moral disagreement. As a result, a compelling case for descriptive relativism will require a sufficiently deep understanding of human psychology to reasonably conclude that many moral disagreements are irresolvable in principle. However, demonstrating descriptive relativism's dependence on psychological research and the importance of evolutionary psychology will first require an understanding of the particular theoretical and empirical obstacles the hypothesis faces.

Descriptive relativism, like every other empirical hypothesis, is vulnerable to the charge that it is underdetermined by available data (Newton-Smith and Lukes 1978; for discussion, see Acuña and Dieks 2014; Kukla 1996; Ladyman 2002, Chap. 6; Laudan 1990; Laudan and Leplin 1991). There is always a way to fit empirical evidence to a hypothesis provided an individual is willing to shift the rest of their beliefs accordingly. This means that for any scientific explanation of a given set of data, there will always be alternative explanations that are consistent with the data. As a result, we cannot interpret the implications of empirical data without implementing explanatory virtues that help us decide among competing accounts of the same data, such as simplicity, precision, scope, and conservatism (the minimization of changes to existing beliefs) (Lipton 2013; Sklar 1975). This by itself is not a significant cause for concern for any particular hypothesis, since the same general worry is applicable to science as a whole, but Michele Moody-Adams (2001) argues that descriptive cultural relativism is especially subject to concerns about

underdetermination, and some of these arguments may apply to descriptive individual relativism as well.

Moody-Adams (2001) notes that anthropological fieldwork often relies on limited access to a small number of interviewees, which raises questions about the representativeness of their responses. Sometimes this is justified on the grounds that members of a community are legitimate authorities on its beliefs and customs. Moody-Adams objects, noting that, "Any such confidence embodies a complex evaluative stance that will sometimes prove neither methodologically nor morally benign. Very often such confidence overlooks the possibility of internal conflict, as when a community practice has been subjected to criticism from within" (p. 95). Authority figures would not represent internal dissent and may not report on it. Yet dissent may represent an ongoing debate within the community that could reveal that some belief or practice is inconsistent with values that are more central to the culture's identity than the practice itself (p. 95). Communities may include subgroups that differ in important ways from designated spokespersons or typical members of the community. For example, interviewing the exclusively male leadership of a highly patriarchal society could overlook the critical and ongoing dissent among women and consulting the typical, reasonably well-off member of a highly economically stratified society may fail to capture the moral perspective of its most disadvantaged members. Attempts to provide a complete picture of the moral values of a given culture would require a more comprehensive analysis of its members and may require contestable appeals to evaluative judgments.

A complete and reliable picture of a culture's moral views is further impeded by linguistic and conceptual barriers that make intercultural interpretation exceptionally difficult. Any attempt to make cross-cultural comparisons will have to account for differences in local conceptions of what constitutes sex, slavery, consent, work, and other concepts relevant to morality, as well as differences in how people conceive of morality itself, including notions about justice, equality,

and purity, as well as differences in epistemic norms, religious beliefs, and a host of ancillary beliefs and practices relevant to their moral perspective. In many cases, this may make it difficult to determine what observations provide relevant information about a culture's moral beliefs and practices or if they even conceive of a given practice as moral at all. As Moody-Adams points out, "... [M]oral relativists seldom hesitate to assume that the natural languages of the groups they encounter contain a concept of morality ... [B]ut this assumption (however plausible) presupposes sophisticated judgment about a concept – the concept of morality – so complex that its content is [essentially contested] ... even by speakers of the same language" (p. 94).

A more pressing difficulty for descriptive relativism is disagreement itself. As previously noted, it is unclear how much moral diversity results from disagreements over nonmoral facts. Given extensive variation in education, cultural background, social class, religious belief, and political ideology, such differences are likely to be extensive both within and between cultures. More importantly, every person and every society are in a considerable state of ignorance about the consequences of their moral practices and of innumerable nonmoral facts that are potentially relevant to their moral systems. Even the most advanced nations have not reached consensus on the long-term consequences of their economic policies or criminal justice systems. Because of this, many moral disputes rest on disagreements about the impact of actions and institutions that everyone lacks adequate information about. People can disagree with impunity under these circumstances since nobody can appeal to evidence that decisively confirms their position. Even when evidence is available, disputes may remain unresolved, since any interpretation of that evidence will likely be tainted by motivated reasoning (Kunda 1990; Sunstein et al. 2016) and ideological commitments that impede rational evaluation (Cohen 2003; Kahan 2013; McCright and Dunlap 2011).

Even if factual disputes are set aside, moral diversity would still fail to unambiguously demonstrate fundamental moral disagreement, since

the same moral principles may be consistent with different local practices. One reason for this is that moral diversity is consistent with *local objectivism*. Local objectivism is the view that there is one universal set of objective moral principles, but differences in environmental conditions, psychological characteristics, or other factors may allow or even require that the same moral principle be satisfied in different ways by different individuals or cultures.

One way this can happen is if two cultures with the same moral values develop practices that differ due to local conditions but which conform equally well to their shared moral standards. An isolated island community with a limited food supply and small population may develop strict norms for regulating reproduction out of a necessity to conserve resources and minimize the deleterious effects of inbreeding. In the long run, failure to adopt these practices could otherwise lead to food shortages and poverty. Yet these practices may be inconsistent with the same moral values in communities with more resources and larger populations. Both the isolated island community and larger communities with more resources could place equal weight on the importance of reproductive autonomy and the collective welfare of the community, and agree sacrifices to the former must be made when necessary to promote the latter, yet only the isolated community would need to make this sacrifice in practice.

The same moral values may also be sufficiently general that a wide range of practices are consistent with them regardless of local conditions. If two people wanted to cross a river, one might achieve this goal by building a boat and the other by building a bridge. Provided these methods were equally effective, the same abstract goal (crossing the river) could be achieved by different concrete methods (e.g., a boat or a bridge). In much the same way, different cultures may conform to the same moral goals by developing different sets of beliefs and practices, even if those practices are not specific adaptations to local circumstance. Whether a specific moral practice conforms to the same set of abstract moral principles may also depend on its function in the context of the wider set of norms, beliefs,

and practices of the moral framework it is embedded in. This suggests that determining whether a particular practice is consistent with a given set of general moral values may require holistic evaluation of its interaction with other norms, beliefs, and practices.

It is also unclear what exactly it would mean to say that moral disagreements are sufficiently extensive that they entail descriptive relativism, since there are many ways of quantifying the total amount of agreement and disagreement or weighing the importance of particular norms or principles. We could emphasize judgments about first-order moral practices, like polygamy or abortion, but there may also be disagreements about the moral importance of character traits (e.g., courage, honesty) or differences in more abstract approaches to morality. For instance, Wong (1984) claims that some cultures adopt a moral system grounded in virtue and promoting the communal good, while other cultures ground morality in rights and emphasize individualism and liberty (Gowans 2015).

Morality can also be cast at different levels of generality. People can disagree about concrete moral practices but share the same commitment to abstract universal principles. Even apparent disagreement over relatively abstract moral values such as personal autonomy or promoting the good of the community could dissolve if morality were cast at an even higher level of abstraction. For example, people may value their culture's moral code because they believe it fulfills the more basic moral goal of promoting human flourishing. Disputes between societies that are more collectivist or more individualist may seem to represent quite abstract differences in a moral perspective and could present more viable candidates for fundamental disagreement, but even these may be due to disputes over which overarching perspective was best for the society on a largely shared understanding of what "best" entails. The purpose of even radically different moral systems, even ones that differ on relatively abstract moral values, could still be to promote even more abstract moral goals, e.g., to promote the well-being of its members (Kluckhohn 1955). Individuals or cultures may agree along some axes of morality

but disagree along others, and it is unclear which, if any, take priority, without drawing on contestable application of explanatory virtues and appeals to philosophical arguments or intuitions. This suggests that a given set of moral disagreements could be consistent with some conceptions of descriptive relativism, but inconsistent with others, and there may be no way to decisively argue that one account should be favored over another. If so, this could make the truth of "descriptive relativism" as a general thesis indeterminate.

In light of these difficulties, the prospects for descriptive relativism seem bleak. But the purpose of presenting them is not to show that they cannot be overcome, it is to justify the need for more comprehensive psychological evidence. At the core of descriptive relativism's claim is an empirical assumption that we are psychologically constituted in such a way that we can form mutually incompatible moral frameworks that could not be reconciled even in principle. If this is the case, it must be due at least in part to specific facts about how human minds function, and knowledge of these facts is critical to evaluating the possibility and extent of irresolvable moral differences. In other words, descriptive relativism is a hypothesis about human psychology. Psychological evidence of the conditions in which moral disagreements could be resolved would provide the most compelling evidence for or against descriptive relativism, since only these findings would allow us to determine whether two people or cultures with different moral beliefs would be likely to come to an agreement if they agreed on all relevant nonmoral facts. For instance, knowledge of how moral judgments differ from nonmoral judgments (or if they do), how moral beliefs are acquired, and what conditions are necessary for moral beliefs to change all inform the possibility that people could converge or fail to converge on the same set of moral beliefs if they agreed about the relevant nonmoral facts.

It is beyond the scope of this entry to survey all research relevant to this dispute, but one issue central to determining the extent and scope of moral disagreement is *moral nativism*. Moral nativism, as a general hypothesis, claims morality

is in some respect innate, but precisely what this means will depend on the particular nativist hypothesis (see Joyce 2016c). The most relevant way nativist accounts differ from one another concerns the traits purported to be innate. *Rule nativism* holds that we have an innate capacity for forming specific moral norms, rules, or judgments. This innate capacity consists of domain-specific psychological mechanisms that lead people to reliably develop particular moral judgments and beliefs, such as the belief that committing incest or harming innocent people is morally wrong.

A second, related view claims that certain moral *domains* are innate. These accounts claim that morality is innately constrained to a subset of domains that limit which behaviors and traits can be subject to moral evaluation. Haidt and colleagues have articulated the most widely developed and widely discussed form of domain nativism, *moral foundations theory* (MFT) (Graham et al. 2011, 2012; Haidt 2012; Haidt and Joseph 2004). MFT is typically characterized as having at least five domains: harm, fairness, loyalty, authority, and purity (as well as a proposed sixth domain concerning liberty and oppression, see Iyer et al. 2012; Graham et al. 2011, 2013). Norms in each of these domains may be triggered by distinct, domain-specific cognitive modules that evolved to meet a particular adaptive challenge relevant to that domain, though Graham and colleagues maintain that MFT can be sustained without any deep commitments about modularity or cognitive architecture (see Graham et al. 2013, p. 63). For instance, the *loyalty* domain evolved to facilitate cooperation with members of one's group, while the *purity* domain evolved as a "behavioral immune system" that encourages avoiding substances and activities that increase risk of infection (Schaller and Park 2011; Graham et al. 2013).

Moral foundations theory does not propose that all domains are equally active in every culture but that culture can amplify or attenuate the relative importance of a given domain. For example, Haidt and colleagues argue that American liberals tend to emphasize harm and fairness but assign relatively little importance to the domains of

purity, loyalty, and authority, whereas conservatives treat all five as important (Graham et al. 2009; Haidt 2012; Haidt and Graham 2007). Furthermore, the specific content of the domain is not specified in advance. Cultures may have standards of fairness but differ in their application, e.g., one culture's purity norms may include specific dietary or sexual taboos that differ from another culture. Finally, MFT incorporates Haidt's social intuitionist model (SIM) of moral judgment. According to the SIM, moral judgments are the result of rapid, automatic, relatively effortless intuitive processes (*system 1 processes*) rather than deliberative, effortful conscious reasoning (*system 2 processes*) (Kahneman 2011; Stanovich and West 2000). Moral reasoning that involves deliberative processes does occur, but it serves primarily to justify and explain our moral beliefs, not to enable us to seek moral truth (Graham et al. 2013; Haidt 2001).

Toolkit nativism holds that we have an innate capacity for thinking in moral terms and to employ *moral concepts*, but these concepts are not limited to any particular domains and do not specify particular moral norms or judgments. (Prinz refers to this form of nativism as *minimal* (Prinz 2009) or *weak* (Prinz 2014). Joyce (2013) objects to this characterization, arguing that it produces the rhetorical effect of making its proponents appear to have retreated from bolder nativist hypotheses and are desperately attempting to salvage a losing position.) Instead, "the individual's socialization process," as Joyce puts it, serves "as the sole determinant of to which subjects these concepts get attached" (p. 131). Concepts like "moral wrongness," "moral duty," and "moral praiseworthiness," may be innate, but whether we regard it as morally wrong to own slaves and morally praiseworthy to help strangers, or vice versa, will depend on our social environment (Joyce 2016c).

All three forms of nativism conflict with anti-nativist accounts. Anti-nativists accounts deny that there are any adaptations for distinctively moral thought or that moral norms, domains, or concepts reliably emerge as a result of innate psychological processes. Prinz articulates one such view. According to Prinz (2009), morality

is “a by-product of capacities that were evolved for other purposes. Morality is a spandrel. There is no mechanism dedicated to the acquisition of moral norms.” (p. 168). Such accounts may hold, like Prinz, that morality is a by-product of domain-general processes, though anti-nativist hypotheses do not necessarily endorse the view that the human mind is a *tabula rasa* or “blank slate” that consists *only* of domain-general processes (Barkow et al. 1992). For example, Machery and Mallon (2010) suggest that the human mind may lack an innate capacity for distinctively moral cognition, but there could still be an innate capacity for normative cognition in general. Machery and Mallon point out that normative thought is not restricted to morality. We also routinely employ normative judgments about rationality (“You should not believe everything you read”), aesthetics (“You should not wear that ugly sweater”), and social conventions (“You should not eat with your hands at the dinner table”) (p. 21). Even if moral norms or concepts in particular were not innate, the human mind could still possess an innate capacity for employing normative concepts, e.g., “oughtness,” with the social environment determining the specific normative domains a particular individual or culture employed. If so, morality would be a by-product of more general psychological processes, but these processes would still be canalized, species-typical traits that reliably emerged across cultures.

Each of these hypotheses has distinct implications for descriptive relativism. For obvious reasons, rule nativism presents the greatest potential threat. If the human mind is equipped with psychological mechanisms that reliably lead most people to adopt a shared set of moral principles, then, depending on how great of a proportion and how central these innate moral norms were to our moral systems as a whole, this could directly entail that descriptive relativism is false. However, rule nativism is not necessarily inconsistent with descriptive relativism. If only a few relatively specific moral norms were innate, other norms could be free to vary between individuals or cultures. If so, moral variation could still be sufficiently widespread to justify descriptive

relativism. A rule nativist account would also need to demonstrate that these innate moral rules are species-typical traits that are universal or nearly universal and that they reliably emerge in a wide range of contemporary social environments, since novel environments may lead some populations to develop different moral norms (Haraway and Maples 1998). As Joyce (2016c) points out, “[...] innate traits may well require substantial environmental input – input that may have been reliably present in the EEA [Environment of Evolutionary Adaptedness] but is absent, patchy, or distorted in the modern environment” (p. 132).

The generality or specificity of an innate moral rule also matters. If a handful of moral rules are innate but relatively specific, such as a norm against incest, these innate rules may fail to capture broad swaths of potentially variable judgment that doesn’t fall within their limited purview. However, a small number or even a single general moral principle could underlie all or nearly all moral judgment. Moral dyad theory (MDT) provides one such unifying account of morality (Gray et al. 2007, 2012a, b, Gray et al. 2014; cf. Crone and Laham 2015). According to Gray and colleagues, all moral judgments are the product of a dyadic template in which an agent intentionally causes suffering to a patient (Gray et al. 2012a). This cognitive template operates even when no obvious moral agent or patient is available by inserting an imagined perpetrator or victim into the act, a process Gray and colleagues refer to as “dyadic completion” (Gray et al. 2014). This allows MDT to explain seemingly “victimless” moral violations, such as homosexuality and masturbation. MDT seems to provide a direct challenge to descriptive relativism. Gray et al. (2012a) allude to this possibility when they state that viewing harm as the currency of morality implies that:

[T]here is not an unbridgeable gap between moral judgments across relationships [...] or cultures [...]. Just as Pesos can be converted to Euros, so too can moral violations across cultures be compared on perceptions of harm. Thus, liberals and conservatives may not fundamentally misunderstand each other’s moral judgments but instead simply disagree on what is harmful. (p. 209)

If so, then all moral disputes would be reducible to factual disputes about what causes harm, which suggests that all moral disagreements could be resolved in principle. Even so, it would remain an open question whether people possessed the psychological resources to resolve moral disputes in practice. Even if the cognitive processes involved to moral judgment were uniformly based in judgments about harm, concrete moral judgments about specific moral issues may be insensitive to this discovery or to information about how harmful an act is. If, for instance, the social intuitionist model or Prinz's anti-nativist view is correct, moral norms are acquired through mechanisms that would make rational resolution to moral disagreements difficult or impossible. Prinz (2009) argues for this explicitly when he states that variation between cultures "[...] may be impossible to rationally resolve. Moral norms are products of nonrational enculturation, not deliberation and deduction from shared first principles," which, he concludes, "amounts to a strong form of descriptive moral relativism" (p. 187). If moral norms are acquired this way, different populations will attach intrinsic importance to different concrete moral norms or otherwise develop rigid commitments to first-order moral beliefs. For instance, an individual raised in one culture may adopt that culture's condemnation of homosexuality, while someone raised in a different culture could adopt their culture's acceptance of it. Even if both of these beliefs were grounded in a harm-based template, information about the harmfulness of homosexuality may be insufficient to sway either individual to adopt the other's beliefs, since the mechanisms involved in norm acquisition would be insensitive to the domain-general processes involved in reasoning and philosophical reflection.

Domain relativism could also support descriptive relativism. If different cultures assign differential weight to or assign variable relevance to one or more domains, this could produce irresolvable intercultural differences in moral value. This possibility would be especially likely if the social intuitionist model is correct, since the SIM suggests that moral beliefs generated by intuitive processes are resistant to conscious revision.

While Haidt does not deny that we can reflect on and revise our moral beliefs, it is unclear whether such processes permit complete malleability in our moral commitments.

Toolkit nativism and anti-nativist hypotheses are consistent with descriptive relativism, though neither, if correct, would guarantee relativism. On either view, the moral content of different moral frameworks may vary between individuals or cultures, since the local social environment determines the content of an individual's moral beliefs. Yet this is consistent with the possibility that members of different social environments could converge on the same moral standards. Absent additional psychological facts about how moral norms are acquired and internalized, and how subject they are to change, views about the flexibility of moral beliefs could cut both ways. The very cognitive malleability that allows a person in one culture to develop a different set of moral beliefs than someone in another culture may also allow those individuals, under the right circumstances, and given further facts about the psychological mechanisms involved in moral judgment and moral disagreement, to reach agreement. FitzPatrick (2014b) points out that even if evolution played a substantial role in shaping the mechanisms involved in moral judgment "[...] This is entirely compatible with thinking that thousands of years of cultural evolution, including the development of sophisticated traditions of moral inquiry and reflection, have also allowed us to engage in largely *autonomous* moral thinking" (FitzPatrick 2014b, p. 242). FitzPatrick adds that we do seem to engage in this type of autonomous thinking when we pursue philosophy, mathematics, and science, and each of these areas of inquiry consists in the discovery of and convergence on a unified set of facts (FitzPatrick 2014a, b, 2015). If moral thinking falls within the ambit of domain-general processes, it is at least possible that the same capacities that permit convergence in math and science could also lead disparate individuals and cultures to converge on the same moral standards.

Descriptive relativism begins with the observation that there are significant moral differences across cultures or between individuals within the

same culture. The critical empirical question is not whether this is true or whether people are willing to fight and die on behalf of conflicting moral values. These issues have been settled with a decisive “yes.” Rather, it is whether the psychological mechanisms involved in the acquisition of moral belief and the resolution of moral disagreement involve a shared set of universal moral commitments, or a shared capacity to track the same set of objective moral truths, that would permit, at least in principle, all societies and all psychologically normal people to come to an agreement.

Evolutionary Psychology and Metaethical Relativism

Evolutionary psychology has both direct and indirect implications for metaethical relativism. Since most arguments for metaethical relativism rely on the claim that descriptive relativism is true, one way evolutionary psychology can play an indirect role is by supporting or casting doubt on the existence of fundamental moral disagreements (see Harman 1996; Prinz 2007; Wong 1984, 2009). One way of establishing metaethical relativism is to identify cases where people reach moral conclusions without any errors in their reasoning or mistaken judgments about the world. If conflicting moral perspectives can be rationally maintained, this suggests that neither position is objectively correct. Arguments along these lines rely on identifying plausible real-world instances of such “faultless” moral disagreements in which neither side of a moral dispute is demonstrably mistaken (Gowans 2015; Kölbel 2004). This reliance on descriptive relativism leads Gowans (2015) to suggest that metaethical relativism would lose most of its supporters if descriptive relativism were refuted. Metaethical relativism would not be decisively refuted even if descriptive relativism were rejected. Some arguments for metaethical relativism do not depend on the prevalence of moral disagreement (see Harman 2000; Rovane 2011, 2013; Velleman 2013). Others appeal to the hypothetical possibility of rationally defensible disagreement (Pojman 2004). If a single civilization came to dominate the world and impose the same cultural standards on everyone, there may be no moral disagreements, but moral

principles would not become objective merely because rival positions had been eliminated. If this were to happen, Pojman insists, “We could still *imagine* a culture that was an exception to the rule and be unable to criticize it” (p. 248). Metaethical relativists could also argue that intelligent extraterrestrial species would have faced different evolutionary pressures that would plausibly lead them to develop different moral values. This suggests that fundamental moral disagreements may be possible even if we cannot identify any among human populations.)

Evolutionary psychology also has important implications for moderate metaethical relativism. These hybrid accounts allow conflicting moral systems to be true but within objective limits imposed by human nature (among other constraints). Foot (2001, 2002), Nussbaum (1993), Wong (1995, 2009), and Velleman (2013) all ground objective moral constraints in empirical facts about what promotes a good human life. For example, Wong’s pluralistic relativism requires moral systems to promote cooperation and individual flourishing. Wong emphasizes that knowing which moral systems can achieve these ends in practice requires a detailed empirical understanding of the particular goals, needs, and desires imposed on the human species by its distinct biological and psychological characteristics, which leads him to explicitly conclude that moral theory must be integrated with empirical findings in evolution and psychology. Although Wong is hesitant to endorse specific evolutionary psychological accounts, empirical facts about human psychology float free of his particular stance and ultimately determine the conditions that optimize human flourishing. Wong is cautious not to explicitly endorse particular evolutionary psychological theories, however. He states that his “use of evolutionary theory [...] should not be confused with an endorsement of some of the most prominent theories of evolutionary psychology that do hold in central, universal psychological adaptations that evolved in the Pleistocene era and remain unchanged to this day” (p. 102). Wong cites Tooby and Cosmides’s (1992) “cheater detection module,” and Buss’s (2003) argument that men and women evolved

distinct preferences for different characteristics in mates as two examples, clarifying that “No argument in this book presupposes the truth of such assertions.” Nonetheless, Wong is confident that the liberal, Western conceptions of morality that dominate philosophy, such as Rawls’s *A Theory of Justice* (Rawls 1971), fail to account for the importance of community and family impressed upon us by natural selection. Aside from Wong’s account in particular, a persuasive case can be made that any attempt to limit moral systems on the basis of empirical facts about what promotes human well-being will depend heavily on evolutionary psychological insights into human motivation and behavior. Utopian dreams of abolishing familial bonds and parochial favoritism in favor of a more global, egalitarian social system may fail if familial affection and in-group favoritism are less susceptible to social conditioning than proponents of social constructivist approaches believe. Likewise, an evolutionary perspective can provide critical insight into the likely function, scope, and malleability of retributive impulses, feelings of jealousy, guilt, and shame, and virtually every other aspect of human psychology relevant to human well-being, insights that may be critical in prescribing norms and policies that do not backfire by failing to take proper stock of human limitations.

One critical response may be that these phenomena can be understood without adopting an explicitly evolutionary approach. However, the value of an explicitly evolutionary approach to psychology lies less in its formal necessity in understanding proximal psychological mechanisms than in understanding how these mechanisms are likely to operate under novel environmental conditions, in providing a deep well of theoretical resources for generating novel hypotheses and for its capacity to narrow the range of plausible hypotheses by providing a background of theoretical and empirical considerations that serve as a check on the plausibility of existing psychological theories, explanations, and phenomena.

To consider just one example of how evolutionary psychology can provide a novel insight into the conditions most likely to be conducive to

human well-being, Wright (1994) argues that conservative preference for traditional monogamous marriage and the nuclear family may reflect a deeper wisdom about human nature, even if progressive and liberal policies are usually more consistent with promoting collective human welfare. Men and women in ancestral environments faced distinct adaptive challenges with respect to mate selection, which culminated in an evolved preference in men for women who are young, healthy, and attractive and a preference among women for men who have high status and the ability to provide resources (Buss 1995). According to Wright, these differences influence the dynamics of the marriage market in polygamous and monogamous cultures. Wives will be less evenly distributed in polygamous societies, since many women benefit more from being a second or third wife to a wealthy, high-status man than the exclusive wife of a lower-status man with fewer resources. As a result, many men on the lower social rungs will remain unwed. Wright argues that this would have significant negative consequences for society, since marriage can exert a pacifying effect on men who would otherwise be more likely to engage in risky behavior and commit more violent and nonviolent crimes (Daly and Wilson 1990, 2001). Wright’s thesis is supported in part by evidence that a high male to female sex ratio is associated with increases in violent crime (Hudson and Den Boer 2004) and that marriage is associated with decreased crime (Burt et al. 2010). These effects may be quite dramatic. Sampson et al. (2006) found that “being married is associated with an average reduction of approximately 35% in the odds of crime compared to nonmarried states for the same man” (p. 465; but see Schacht and Kramer 2016 and Schacht et al. 2014 for more recent criticisms of the impact of sex ratios on crime).

Wright argues that contemporary liberal societies have become increasingly permissive of divorce, premarital sex, and a generally lax attitude about sexual behavior. The net effect has been an abandonment of traditional marriage and slide into serial monogamy, which has similar social consequences as polygamy, since serial monogamy allows high-status men to monopolize

the peak fertility of young women before moving on to younger mates (p. 101). In short, Wright argues that a strong norm of institutionalized monogamy would provide a bulwark against the socially destructive behavior of unwed men (pp. 101–102). Even if Wright is incorrect, his analysis reveals the potential for an evolutionary psychological perspective to uncover reasons to reevaluate the social impact of institutions we might have otherwise overlooked.

Findings in evolutionary psychology could also cast doubt on metaethical relativism by supporting forms of moral realism that are incompatible with it. At a minimum, moral realism holds that moral claims can be true or false, and at least some of these claims are true (Sayre-McCord 2015). (More specifically, moral realists hold that at least some first-order moral claims are true, e.g. “murder is wrong” (see Bennett 1998, p. 46). An anti-realist could acknowledge that some claims about morality can be true, e.g. “There are no moral truths,” but this does not constitute moral realism.) Not all conceptions of realism are necessarily incompatible with metaethical relativism (Harman 2015), and this minimal definition is consistent with metaethical relativism (see also Joyce 2015). (Joyce (2015) makes this point plainly, stating that “Moral relativism is sometimes thought of as a version of anti-realism but (short of stipulating usage) there is no basis for this classification; it is better to say that some versions of relativism may be anti-realist and others may be realist.”) However, moral realism is typically construed (and will be understood here) more narrowly as the claim that moral facts are “objective features of the world,” which we are capable of discovering and which are not dependent on or constituted by beliefs, preferences, or evaluative attitudes (Joyce 2016a, p. 5; Sterelny and Fraser 2016; Street 2006). Since moral realism in this narrower sense purports to establish the existence of a universal body of objective moral facts that are true for all people and cultures independent of their individual or cultural moral standards, any such account would entail an explicit rejection of metaethical relativism. Several attempts have been made to establish this more narrow conception of moral realism by appealing to human evolution (Collier and Stingl 1993, 2013;

Harman 2000; James 2009; Sterelny and Fraser 2016; Zamulinski 2007). Collier & Stingl refer to this approach as *evolutionary moral realism*, which they define as “the view that there are moral values with roots in evolution that are both specifically moral and exist independently of human belief systems” (p. 218). Sterelny and Fraser (2016) present one of the most developed accounts of evolutionary moral realism (Joyce 2016a). They argue that the moral cognition evolved primarily to identify “facts about profitable forms of cooperation, about social arrangements and cognitive dispositions positively and negatively relevant to the stable exploitation of those opportunities” (p. 10). The success of accounts like these depends critically on whether the facts of human evolution are consistent with them. If we did not evolve an innate capacity for distinctively moral cognition, or if we did, but this capacity does not function in part to detect facts about which policies, actions, and attitudes facilitate cooperation, Sterelny and Fraser’s account would fail for the simple reason that it rests on mistaken empirical presuppositions about the evolution of human moral cognition. But if they do correctly identify the facts of human evolution, one of these accounts could succeed at establishing an objective set of moral truths that would disqualify metaethical relativism as a viable philosophical position.

Even so, some of these accounts may provide an incomplete picture of morality that allows some room for fundamental moral disagreement. Sterelny and Fraser (2016) claim only that *one* of the primary functions of moral cognition is to track facts about cooperation. If, as they concede, our moral faculty only partially and imperfectly tracks facts about cooperation, this leaves open the possibility that there are other aspects of morality that cannot be fully incorporated into a realist account of morality. Sterelny and Fraser seem open to this possibility, rejecting the strict dichotomy between evolutionary influences on human moral thought either fully vindicating or fully debunking moral realism (p. 4). A moderate form of metaethical relativism could potentially escape partial realist accounts of this kind, if they can identify plausible instances of fundamental moral disagreement that fall outside the scope of

the truth-tracking aspects of moral cognition. (It also seems that evolutionary moral realist accounts may not escape being relativized to the *species* (see Harman 2000). If so, it is unclear how these accounts would manage interspecies moral disagreements. If moral facts *just are* the sorts of facts captured by human linguistic conventions, however, then one move may be to argue that another species with radically different values isn't really engaged in *moral* cognition but a conceptually analogous form of normative cognition that could similarly track its own independent set of normative facts.)

In contrast to arguments for evolutionary moral realism, *evolutionary debunking arguments* (EDAs) attempt to undermine moral realism by demonstrating that moral beliefs are false (Ruse 1986, 2006) or unjustified (Joyce 2006; Street 2006). Street (2006) presents one of the most widely discussed EDAs in the form of a dilemma for moral realists. Street begins with the premise that some form of moral nativism is true or at least that evolution has so extensive an influence on moral judgment that that "our system of evaluative judgments is thoroughly saturated with evolutionary influence" (p. 114). She then poses the following dilemma to moral realists: either there is no relationship between evolutionary influences on moral judgment and the independent set of objective moral facts posited by the realist or there is a relationship. If there is no relationship, then it would be an extremely unlikely coincidence if our moral judgments happened to track objective moral facts (Joyce 2016a). If there is a relationship, then moral judgments could track moral facts. Street refers to this second horn of the dilemma as the *tracking account*. Street believes that this is the more plausible of the two horns of the dilemma but that, unfortunately for the realist, available empirical data does not support it. Evaluating Street's argument is not critical here. The only relevant point is that both EDAs and evolutionary moral realism fail if they rest on mistaken assumptions about the evolution of human moral cognition. In short, these accounts rely on empirically falsifiable evolutionary psychological presuppositions, and to that extent they are all

fundamentally dependent on evolutionary psychological findings.

Fraser (2014) has criticized proponents of EDAs for failing to grapple with the relevant evolutionary details and proposes a minimal set of conditions necessary for the evolved cognitive mechanisms involved in moral judgment to reliably track moral truths. This represents genuine progress in identifying the empirical questions both moral realists and antirealists would need to answer. But the conditions Fraser identifies presuppose that we are adapted to engage in distinctively moral judgment. Machery and Mallon (2010) distinguish this strong nativist position from two alternative conceptions of what it would mean to say that "morality evolved." To say that morality evolved could mean that some of the underlying mechanisms involved in moral judgment (but not necessarily *only* moral judgment) evolved (p. 4). Likewise, normative cognition, understood as the "the capacity to grasp norms and to make normative judgments," may have evolved (p. 4). If so, there may be no specific evolved faculty for distinctively *moral* normative judgments. (Sinnott-Armstrong and Wheatley (2014) defend the even stronger claim that there is no conceptually unified domain of "moral norms" at all.)

Millhouse et al. (2016) argue that if a capacity for distinctively moral cognition did *not* evolve, this presents a significant obstacle for EDAs. If moral cognition results from a domain-general capacity for normative cognition, arguments that undermine moral truth may also undermine other evaluative truths, including the very epistemic norms that would permit people to make rational judgments in the first place. Any EDA that seeks to establish that *only* moral norms are threatened in this way must therefore either show that moral cognition is a distinct capacity or provide a principled means of debunking *only* moral judgments but not other normative judgments. Millhouse et al. refer to this as the *containment problem*. On the other hand, if some of the underlying components involved in moral cognition evolved, each may have a different evolutionary history and adaptive function. If so, debunking arguments that cast doubt on the reliability of specific mechanisms

will have to target each of these mechanisms separately to show that that mechanism in particular cannot reliably track moral facts. This opens up the possibility of more targeted evolutionary debunking of specific features of moral judgment. For instance, if Greene's dual process model of moral cognition is correct, then moral judgments may result from two relatively distinct psychological processes, each of which may have a unique evolutionary history and may have evolved to meet a specific adaptive challenge. An evolutionary debunking argument may succeed at undermining one of these domains without undermining the other. In short, if moral cognition is the result of a disunified set of cognitive processes, it may be possible to debunk some moral judgments without debunking others.

Evolutionary Psychology and Normative Relativism

The truism that one cannot derive normative conclusions from descriptive facts is no less applicable to the relationship between evolutionary psychology and normative relativism (Hume 1739; Schurz 1997). Although the moral duty to tolerate people and cultures with different moral practices cannot be derived directly from facts about the evolution of moral cognition, evolutionary psychology still has indirect implications for normative relativism. Arguments in favor of normative relativism are often predicated on the truth of descriptive relativism, metaethical relativism, or both. Insofar as evolutionary psychology supports or undermines either, it will have an indirect influence on arguments for normative relativism.

Evolutionary psychology also has the potential to provide practical insight into how to devise and implement policies and interventions that effectively promote intercultural and interpersonal tolerance of moral differences. Even if we arrive at the normative conclusion that tolerance of moral differences is desirable, the practical question of how best to conform to this norm will depend on relevant psychological considerations. Research on the developmental psychology (e.g., Aboud 2003; Bigler and Liben 2007; Cameron et al. 2001; Rutland et al. 2010), social psychology (e.g., Brown 2011; Devine 1989; Greenwald

and Banaji 1995), and neuroscience (e.g., Amodio 2014; Baumgartner et al. 2015; Ratner et al. 2014; Sellaro et al. 2015) of prejudice, stereotyping, and intergroup biases can and already has been usefully integrated with moral psychology (Van Nunspeet et al. 2014) and supplemented by an evolutionary perspective (Fiske 2000; Kaya 2015; Kurzban and Neuberg 2005; Kurzban et al. 2001; Mahajan et al. 2011).

Park (2012) has already made an explicit effort to extract practical guidance from an evolutionary psychological perspective on tolerance. An evolutionary perspective on prejudice suggests that there may be systematic differences between forms of prejudice related to intergroup interaction (e.g., racism) and forms of prejudice that are not (e.g., sexism) since the former may draw on evolved mechanisms uniquely adapted to coalitional psychology. If different forms of prejudice rely on different psychological mechanisms, understanding the evolutionary origins and likely function of these mechanisms may be relevant to devising effective interventions. As Park notes, "A broader implication of evolutionary perspectives is that there is unlikely to be a panacea for reducing every kind of prejudice. The best methods will differ for prejudices against ethnic out-groups, women, elderly people, gay people, obese people, disabled people, and non-human animals, because the roots of these prejudices differ" (p. 195).

Conclusion

The philosophical relevance of empirical data has become an increasingly contested topic in contemporary philosophy. The rise of experimental philosophy (Knobe and Nichols 2013), which utilizes social scientific methods to explore traditionally philosophical questions, has prompted widespread reflection and reevaluation of the methods and characteristics that make philosophy a distinct academic discipline. Recent attempts to draw philosophical conclusions from moral psychology (e.g., Greene 2003) have likewise challenged traditional assumptions about the relationship between moral psychology and moral philosophy. An

evolutionary psychological perspective will likely play a growing role in understanding the relationship between psychology and philosophy in general. In reviewing the relevance of evolutionary psychology to the different forms of moral and cultural relativism, this entry has outlined one small facet of this broader picture.

Cultural Cortical Recycling Hypothesis Applied to Money

Cultural evolution; Monetary artifacts; Neural recognition systems

Definition

The cultural cortical hypothesis states that neural mechanisms, which were used in evolutionarily ancient environments for the recognition of natural visual categories like faces and food items, have now been recycled for recognition of more recent cultural artifacts, like money.

Introduction

Money is a recent institution – circa the seventh century BC, in Lydia for its apparition as coins (Kagan 1982; Pavlek et al. 2019) – fit to facilitate anonymous and out of group transactions. In shaping such transactions, money performs the function of shaping relationships with our conspecifics and, in turn, our social environments. But despite the ubiquity of money and economic institutions, it is evolutionarily ancient psychological traits like altruism, reciprocity, and cooperation which are most widely studied, both conceptually and empirically, to understand human social institutions. Little knowledge has been acquired on the biological anchoring of more recent economic institutions, like money and the social artifacts that support their functioning. A default hypothesis would be that they are a specific and autonomous development from our basic neurobiological and cognitive fabric. But it remains largely obscure as to *how* these biological mechanisms have been involved in the emergence of economic mechanisms that seem to lie far beyond their purview.

The Main Hypothesis

The hypothesis we advance here, in the particular case of monetary artifacts, is that of an epigenetic nature. Since one of the fundamental modes by which we relate to these artifacts is through perception and recognition, evolutionarily selected mechanisms in the visual system – dedicated to the perception of survival-oriented features in ancestral environments – are cortically recycled

to process these novel cultural items, vital in our modern economic environments. It must be noted that this does not exclude the role of social cognitive mechanisms driving monetary exchanges, which affect and bias the theoretically neutral use of money in important ways and are supported by modern artifacts like coins (Rumiati and Lotto 1996) and other monetary media. However, to be efficient, coins need to be efficiently and promptly identified, and the cortical recycling hypothesis can provide a biologically rooted, theoretical basis for the same.

The cultural cortical recycling hypothesis has hitherto been confined to other symbolic systems such as literacy and numeracy (Dehaene and Cohen 2007), which promote the idea that part of the human cortex is specialized for cultural domains such as reading and arithmetic. Though the apparition of these cultural domains is too recent to have influenced the biological evolution of the human brain, brain activations associated with these symbolic stimuli have been shown to demonstrate a reliably high degree of invariance. To account for this seeming paradox, the cortical recycling hypothesis is proposed, according to which cultural inventions invade evolutionarily older brain circuits and inherit some of their structural constraints. In this article, we speculate about the extension of this hypothesis to money and other symbolic aspects of our economic lives.

A Seminal Experiment

We briefly report on an experiment, demonstrating fast and automatic detection of the validity (or invalidity) of unfamiliar coins, in a subregion of the brain visual system – the fusiform gyrus. We show the existence of symbolic activities in the fusiform gyrus, associated with the visual categorization of monetary stimuli.

Tallon-Baudry and colleagues (2011) tested the perception of valid coins (euros and Australian dollars) versus invalid ones (French francs and Finnish marks, which have been out of circulation since 2002) using magnetoencephalography (MEG). Since coins are both material and symbolic objects endowed with economic properties by social agreement, abstract and

artificial features such as *coin validity* were expected to be analogous to words and their meanings. Moreover, since symbolic categories are conventional, they were expected to be differently processed than ecological categories which are based on visual similarities, like faces, food, and animals. It was expected that monetary stimuli would be decoded with a minimal 300 ms delay, similar to categorizing a letter string in one's natural language (Allison et al. 1994) and different from categorizing natural objects, which occur within a 150 ms delay (ibid.). Surprisingly, it was found that both familiar and unfamiliar coins were readily recognized and differentiated within 150–175 ms, similar to natural categories, indicating that there preexists a neural representation of money sufficiently generic and abstract to accommodate new instances. Thus, familiarity with specific categorical instances of valid or invalid coins was not a requisite for money recognition. These results suggested that the human ventral visual system is adapted to deal with symbolic environments, or at least certain objects such as coins, on the basis of general knowledge rather than long reinforced experiential channels.

Inter-species Comparison

This raises the question as to whether such mechanisms and observations are human specific or can be found in other species as well, with comparable visual neural organization. Do species, which flexibly use tokens in exchanges, display a similar ability to categorize the validity of these tokens on a mere perceptual basis? De Petrillo et al. (2019) studied six capuchin monkeys (*Sapajus* spp.), who were required to exchange valid/familiar tokens, valid/unfamiliar tokens, invalid tokens, and no-value items with the experimenter. They first exchanged a similar number of valid/familiar and valid/unfamiliar tokens, followed by exchanges of invalid tokens and no-value items. And just like humans, capuchins readily recognized token validity, regardless of their familiarity with these tokens. Time delays in the use of valid/unfamiliar versus valid/familiar tokens in the task were nonsignificantly different, evidencing the neurobiological capacity of non-human primates in promptly acquiring and

visually tapping into abstract monetary features, independent of long-term reinforcement.

In a sequel experiment, the authors evaluated the flexibility of the token–food association by assessing whether capuchins could engage in reverse food–token exchanges. This was done to study how rapid detection of monetary validity could be associated with actual proto-monetary behavior. Subjects spontaneously performed chains of exchanges in which a food item was exchanged for a token, and then the token was exchanged for another food item. Overall, capuchins recognized token validity and successfully engaged in chains of reverse and direct exchanges. This suggested that although non-human animals are far from having full-fledged monetary systems, for capuchins, tokens share at least some features with human money and can be promptly recognized as valid or invalid on a perceptual basis.

Adapting the Cultural Cortical Hypothesis

In order to explain such results, we put forward the idea that some specific cortical maps dedicated to basic perceptual functions could have been re-used at some point in relatively recent human history, for the purpose of processing novel cultural items (Dehaene and Cohen 2007). In other words, specific brain areas crucial for human survival in hunter-gatherer societies were recycled in view of optimal visual recognition of monetary stimuli. This would further suggest that there isn't a complete discontinuity between the cognitive and neurobiological mechanisms that bore upon exchanges in pre-monetary economics and the ones that prevail in modern times. From a neural point of view, our findings may indicate that the so-called ventral visual pathway, a system previously thought to analyze visual features such as shapes or colors in daily experiences, could also utilize conceptual features such as monetary validity in abstract economic exchanges.

The symbolic abilities of the posterior fusiform region suggested here could constitute an efficient neural mechanism to deal with culturally defined

symbols. Moreover, such a hypothesis also holds explanatory value for the success and cultural emergence of money as an extension of evolutionarily anchored and localized processing of natural items such as faces, food, or in the artifactual domain, tools (Stout et al. 2008). The main effect of validity versus invalidity has been documented to be concentrated in the fusiform gyrus. The speculation is thus that a special neural cortical map located in this area may have been selected through evolution to detect whether faces or foods, or anything contributing to the individual's survival in her environment, are of a "valid" or an "invalid" nature. This primitive cortical map may then have been reused in the processing of money stimuli and supported its emergence. Such a neural nesting of money would furthermore help to explain behavioral anomalies that have been often emphasized with respect to this culturally central human artifact, such as perceptual illusions in the guise of money illusion (Weber et al. 2009; Bourgeois-Gironde and Guille 2011).

Conclusion

The application of Dehaene and Cohen's (2007) cultural cortical recycling hypothesis to the visual processing of monetary artifacts is still speculative due to the lack of confirmatory experiments. Nonetheless our economic lives involve an array of symbolic activities, the emergence of which is contemporary with the cultural revolution leading to numeracy and literacy. In that sense it seems reasonable to investigate an adaptation of the cultural cortical recycling hypothesis to a domain of our human activities that has generated its own pervasive cultural items, such as, most centrally, money. A future refinement in the evolutionary approach to economic behavior would consist of an exploration of what we label "continuing temporal overlaps" in our cognitive and behavioral evolution. Using money in modern market transactions jointly taps into very anciently established neural circuits and to modern adaptations of these circuits. This temporal overlap may contribute an explanation to biases, including perceptual ones, that affects our economic behaviors.

Cultural Differences in Mate Preferences

Carlota Batres

Department of Psychology, Franklin and Marshall College, Lancaster, PA, USA

Synonyms

Cross-cultural differences; Culturally variable; Partner preferences

Definition

Cultural differences in mate preferences refer to the variations that arise in preferred mate qualities as a result of cultural influences.

Introduction

Research has found that there are mate preferences that are found cross-culturally. For example, across cultures, symmetry is found attractive (Rhodes et al. 2001). However, studies have also found cultural differences in mate preferences (Batres et al. 2017; DeBruine et al. 2010; Penton-Voak et al. 2004).

Explanations for Cultural Differences in Mate Preferences

From an evolutionary standpoint, preferences are adaptations for mate choice. Therefore, mate preferences should vary depending on culture to reflect variations in the environment. Preferences for body mass index (BMI) have been found to vary cross-culturally since there are differing optimal weights for different environments. For instance, one study found that individuals from Uganda preferred heavier figures than individuals from Greece and Britain (Furnham et al. 2002). In environments with less food certainty, individuals with higher BMIs are found more attractive since they are better equipped to survive and reproduce.

Preferences for masculinity have also been found to vary cross-culturally. For example, one study found that Jamaican women preferred men with more masculine faces than British women (Penton-Voak et al. 2004). Similarly, DeBruine et al. (2010) found that across 30 countries, women's preferences for masculinity were higher in countries with decreased health. There is some evidence that masculinity in men signals health (Thornhill and Gangestad 2006), and therefore, it would be beneficial for women in countries with higher health risks to prefer more masculine partners.

Apart from an evolutionary perspective, urbanization has also been proposed as an explanation for cultural differences in mate preferences. Indeed, urbanization predicts changes in basic perceptual processes (Linnell et al. 2013). Individuals in environments with higher levels of urbanization have increased media exposure, and research has shown that this exposure influences partner preferences (Batres and Perrett 2014).

Lastly, a third explanation that has been proposed to explain cultural differences in mate preferences is familiarity. Studies have found that exposure to certain populations of faces increases the attractiveness of similar faces. For instance, Saxton et al. (2009) found that girls who attended single-sex schools preferred more feminized male and female faces than girls who attended mixed-sex schools. Similarly, another study found that

across El Salvador and Malaysia, individuals exposed to faces with higher adiposity preferred faces with higher adiposity (Batres and Perrett 2014). These results suggest that the visual diet of individuals also influences partner preferences.

Conclusions

Several explanations have been proposed to explain cultural differences in mate preferences. What is clear is that culture does indeed have an effect on preferred partner characteristics. Moreover, those preferences are quite malleable, with changes in the environment resulting in variations in partner preferences (Batres and Perrett 2017). Future research into cultural differences in mate preferences is still needed, but the growing concern about examining partner preferences outside of WEIRD (Western, Educated, Industrialized, Rich and Democratic) populations has already yielded many interesting insights.

Cultural Differences in Sexual Socialization

Diederik F. Janssen
Nijmegen, The Netherlands

Synonyms

[Sex education](#)

Definitions

Sexual socialization refers to the variable extent and many ways mating strategies are communicated and replicated along and beyond generational lines.

Sexual enculturation encompasses induction into any relatively patterned and durable system of elaboration of mating choices as socio-symbolic resources.

Introduction

Formal sex education has a distinct, if relatively short, global history, and although today near-universal, it exists importantly despite near-universal controversy (Zimmerman 2015). Evident cross-cultural differences in sexual socialization have been studied semi-systematically since the late nineteenth century. They triggered strikingly divergent valuations: by Victorian evolutionists, as vignettes of “primitive” promiscuity; by often psychodynamically oriented mid-twentieth-century sexual reformers, to denaturalize what was considered neurosis-inducing Western bourgeois sexual uptightness; by 1970s psychohistorians, claiming that most modes of sexual socialization recorded by historians and ethnographers entailed “child sexual abuse.” None of these readings enjoys much traction today; most controversy rather arises from interpreting comparative data in the light of evolutionary psychological theories of child development and child-rearing inspired by early 1970s “parental investment theory” (Draper and Harpending 1988; Belsky et al. 1991), and subsequently by early 1990s “sexual strategies theory.” Cross-contextual comparisons have been used to demonstrate both ubiquitously recurring patterns and high variability in lifetime reproductive challenges and outcomes. In these comparisons *sexual culture* is considered both to present, and to codify into sexological lore, specific reproductive challenges for parents, for their offspring, and for their prospective mates. These challenges reflect the responsive, yet differentiated, biological-reproductive outlooks of men and women. They simultaneously articulate the symbolic resources available to men and women within social systems providing gender, generational, kinship, and other frames for the allocation of status, resources, and identity.

Mating Contexts

Today, differences between parenting of boys versus girls are generally found to be minimal (Endendijk et al. 2016). In the area of sexuality, however, daughters are ubiquitously raised more restrictively than sons, arguably suggestive of culture-transcending fitness effects (Kuhle et al. 2015). Human and especially female mating strategies are considered highly contextual, in any case, requiring the development and lifelong fine-tuning of *mating intelligence* (Geher and Kaufman 2013) in any context, with usually well-recognized peer-group, parental, grandparental, or avuncular roles (Fisher et al. 2013). Parent-offspring conflicts over offspring mate choice are widespread across human cultures (Van den Berg et al. 2013). Such conflict can be said to create the need to socialize offspring in the direction of mating choices preferred by parents under specific environmental conditions. Enforcing of parental preferences can clearly also precede or otherwise obviate socialization of offspring mate-selection and mate-retention skills. Intrafamilial mating is subject to culture-specific rules, or in any case mechanisms, of avoidance. Other modalities of in-group mating may rather be subject to culture-bound rules of obligation, or less binding qualifications of convenience, appropriateness, or eligibility. These intrafamilial and intergenerational intrigues impress as ubiquitous among humans (Gray and Garcia 2013). They clearly also refer the anthropologist to cross-culturally and historically variable ways of being translated into lore and law. Parental control over mating has dominated most of what is known of human pre-industrial social evolution, and such control continues to exert an overriding sexual selection force, for instance across the Abrahamic religions (i.e., more than half of the world population).

Parental influence extends to a spectrum of key parameters of offspring mating, including mate preference, selection or exclusion (betrothal, arrangement of courtship, and mating trials) timing of mating and child-spacing; postmarital residence; and so on. These dimensions of *parental choice* are characterized by evident differences

between societies of different subsistence types (hunting-and-gathering, agropastoral, industrial and post-industrial economies), but also between and within societies of a similar subsistence type (Apostolou 2017). Child training patterns including those pertaining to sexuality have been shown to vary in ways predictable from evolutionary theory, especially between the sexes, and responsive to such factors as group size, marriage system, and stratification level (Low 1989). In preindustrial contexts, ritualization and coordination of reproductive “crises” (including especially menarche, marriage, and birth of, for instance, future male heirs) voice the interests of not so much *parents* as the wider scope of *fraternal interest groups* (Paige and Paige 1981), or overarching corporate entities such as lineages, clans, moieties, age sets, casts, and tribes. “Sexual socialization” here inclusively translates to all those formal and informal efforts to induct young people into these often starkly gendered and intricately allied political factions, which may in turn entail a dramatic delimitation or even determination of mate and mating choices. As a consequence, eventual mating choices may be interpreted as either articulations of corporate decision-making or as precarious attempts at defying such politics.

Mating Cultures

Parental choice is only one (a receding) facet of, or engine behind, what in twentieth-century Anglophone social scientific parlance was variably known as *sexual enlightenment*, *sexual socialization*, *sex training*, *sex education*, or *family planning*. Its purported objectives have shifted, reflecting a changeable encryption of pedagogical stakes and purviews: *sexual “well-being”* or *“fulfillment,”* *sexual agency*, *sexual self-determination*, unrestrained *“expression of one’s psychosexual identity,”* among other formulations. Living up to these familiar tropes is a uniquely human burden and requires what may more productively be called *sexual enculturation* (compare Konner 2010). It extends to culturally divergent concepts and indices of docility,

distinction, and discretion: beyond inculcation of often gendered traits such as “sexual restraint” or modesty, and including culturally belabored notions of shamefacedness, chastity, reputation, ignorance (“innocence”). In religious and ensuing medical conceptualizations, modes of satisfying the “reproductive drive” are abstracted across such time-honored juxtapositions as natural/unnatural, clean/polluted, and normal/perverse.

Much of this lore remains codified in medical consensus or law (often precariously both), though many contexts for adolescent mating are globally characterized by “stresses and shifts between concepts such as modernization/traditionalism, arranged marriage/free choice, love/family practicality, cohabitation/marriage, and collectivism/individualism” (Hamon and Ingoldsby 2003, p. ix). Within the course of a couple of generations, legislation has globally shifted from protecting the institute of the family from sexual liaisons and practices considered to undermine it, to protecting and disentangling the sex life of individuals from such corporate interference (Frank et al. 2010). In most of recent world history, most adolescents have not been known to cite, or indeed prefer, family as the primary resource for sexual instruction. Pre-adolescent sexual socialization is riddled with avoidance and anxiety, and even today poorly researched (Martin and Torres 2014). In the prolonged sphere of modern child-rearing and adolescent-coaching, makeshift cultural dichotomies reign, notably in the USA, between “good and bad” touch, “appropriate and inappropriate” comportment, “healthy and abusive” intimacies. *Sexual socialization* thus importantly entails not “mate choice” but the pancultural, and today variably international and global, projection and continual renegotiation of these binaries *regardless* of mate choice – unless choice of mates is declared, by cultural convention, impossible per se (such as where involving perceived power unbalances).

Conclusion and Implications

Though culture can be seen as providing solutions to common reproductive challenges, it can also be

said to create, entrench, or significantly complicate these challenges. This notably constrains scientific accounts of the problem. Sexual culture figures forth a socio-symbolic environment which frames reproductive problems in tendentious ways and offers resources for their resolution securely within those frames, with socio-symbolic payoffs and opportunities for some and hardship for others. Mating psychologists and behavioral ecologists might be thought of as decrypting and demystifying these frames. But since researchers and theorists are raised, and have to function, within some sexual culture or another, they typically steer clear of banalizing that culture's most critical sensibilities – today often precisely those gravitating around notions of “sexual and reproductive development” – and most end up crediting the status quo with accolades of presumptive functionality. In this way, *evolutionary psychology* can well function as yet another articulation, or framing device, of contemporary sexual culture, albeit an as yet marginally authoritative one.

[Behavioral evolution](#); [Behavioral inheritance](#); [Cultural evolution](#)

Definition

Cultural inheritance is an inheritance system characterized by the storage and transmission of information by communication, imitation, teaching, and learning.

Introduction

Cultural inheritance is an inheritance system characterized by the storage and transmission of information by communication, imitation, teaching, and learning (Peedicayil 2001). The communication can take place by different routes – visual, auditory, and other routes. The communication can occur by speech, by writing, by a tape recorder (Bonner 1980), and, in today's world, by television, cell phones, and the Internet. The communication can also take place over a considerable distance and over a considerable span of time (Bonner 1980). The communication can be fast or slow. This inheritance system was first proposed by the noted American geneticist and Nobel Laureate Thomas Hunt Morgan (1932). Cultural inheritance is widely present in the animal kingdom, especially birds and mammals. However, it markedly evolved and developed only during human evolution, with the marked increase in the size of the brain, which occurred both in absolute terms and in relation to body weight (Pilbeam and Gould 1974). The increase in size of the brain was associated with the emergence of language (Peedicayil 2002). Cultural inheritance is also referred to as cultural evolution

and behavioral evolution. It can occur by various routes (Jablonka and Lamb 1995): it can be transmitted from parents to offspring (vertical transmission), and to and from other members in the group (horizontal and oblique transmission).

When compared with genetic inheritance, cultural inheritance occurs faster, can occur between any two individuals, and is transmitted by the brain, and not by genes. However, cultural inheritance does have a genetic basis, the genes involved encoding proteins associated with the structure of the brain. Epigenetics, the study of heritable changes in gene expression not involving changes in DNA sequence, is considered to be the link between genetic inheritance and cultural inheritance during the evolution of cultural inheritance (Maynard Smith and Warren 1982).

Criteria to Be Fulfilled for a Trait to Be a Part of Cultural Inheritance

Modern evolutionary biology is founded on the Mendelian genetic model. However, now it is clear that this model is inadequate. Experimental evidence indicates that the environment can impose transgenerational effects and cause heritable variation for a broad range of traits (Bonduriansky and Day 2009). Danchin et al. (2011) have discussed the criteria that need to be fulfilled for a trait to be considered a part of cultural inheritance: (1) The expression of the trait must result from social learning, which is learning learnt from others. (2) Variation in information of the trait must arise from older to younger individuals, allowing the resulting variation in behavior to be inherited. (3) Social learning must modify the phenotype of the learning individual for enough time so that other individuals can observe the behavior and learn it. (4) The modification of the phenotype should be generalized to similar situations. The authors suggest that these criteria provide conceptual and practical tools for identifying cultural traits in order to study the ecological and evolutionary consequences of cultural inheritance.

Cultural Inheritance in Animals

As mentioned above, cultural inheritance is found not only in humans, but, to a lesser extent, also in animals. Obviously, cultural inheritance is only possible in animals with a considerable ability to change their behavior by copying and practice (Manning and Dawkins 1992). It is known that behavior can only evolve if animals differ in what they do and if the difference between them is transmitted from one generation to the next. In that case, natural inheritance can occur, favoring some variants, which hence spread, and eliminating others (Manning and Dawkins 1992). Cultural inheritance is unusual and unique because an animal can learn from its parents or others in its group. Later that animal itself can act as a model from which its own offspring can modify their behavior (Manning and Dawkins 1992). There are several examples of cultural inheritance in primates other than humans. For example, cultural inheritance manifests in the form of sweet potato washing, digging for peanuts, and placer mining of wheat grains in *Macaca fuscata* (found in Japan) (Wilson 2000). Examples among chimpanzees include fishing for termites using a twig, a leaf stalk, or a grass stem (Manning and Dawkins 1992). In orangutans in Borneo and Sumatra, several behaviors like gestures, tool use, and vocal signaling are also thought to be examples of cultural inheritance (Plotkin 2010).

There is now also increasing evidence for cultural inheritance in animals other than primates. A very good example of cultural inheritance in birds is the habit of blue tits to open milk bottle tops, a phenomenon first noticed in the United Kingdom (Manning and Dawkins 1992). Another example is young European blackbirds giving alarm calls to objects like a stuffed owl or a plastic bucket if they had heard their parents' alarm calls while looking at them (Manning and Dawkins 1992). Another example among birds is the maintenance of song dialects of many birds like the white-crowned sparrow (Manning and Dawkins 1992). Yet another example in birds is in New Caledonian crows which display significant cognitive skills in making tools for retrieving otherwise unobtainable food (Plotkin 2010). Cultural

inheritance is also thought to be at work in the phenomenon of vocal and motor imitation in bottle nose dolphins (*Tursiops*) and imitation and teaching in killer whales (*Orcinus orca*) (Rendell and Whitehead 2001).

Cultural Inheritance in Humans

Cultural inheritance is found predominantly in humans among all animals. This is because humans have two interrelated traits that distinguish them from other species: the first is a large brain in relation to body weight, and the second is the ability to communicate with other members of the same species by means of a very well developed language (Blackmore 1999; De Duve 2002; Buss 2008; Lieberman 2016). Language did not develop during human evolution all of a sudden. Before language evolved, a less sophisticated and developed form of language called protolanguage evolved (Jablonka and Szathmáry 1995; Szathmáry and Maynard Smith 1995; Nowak and Krakauer 1999). Protolanguage, when compared to language, is relatively simple, with a poorer grammar and lexicon. It is thought to have first appeared in *Homo erectus*, a precursor of our species *Homo sapiens*. *Homo erectus* appeared in the world about 1 million years ago (Foley 1995). The development of cultural inheritance was associated with an increase in the flexibility of behavioral responses, and was linked with the evolution of mental functions and abilities. It has been proposed that cultural inheritance underlies normal behavior and psychiatric disorders (Peedicayil 2002). Given below is a discussion of the evolutionary aspects of the role of cultural inheritance in normal behavior and psychiatric disorders.

Relevance of Cultural Inheritance to Psychology and Psychiatry

As mentioned above, language and a relatively large brain form the basis of cultural inheritance. The British psychiatrist and researcher Timothy J. Crow suggests that the human capacity for

language could be related to psychiatric disorders like schizophrenia and bipolar disorder. He suggests that such psychiatric disorders could be the disadvantageous spin-off of humans for having a large brain and the ability to communicate with one another by means of a well-developed language (Crow 1995, 2008). Indeed, it is well established that language is an essential and fundamental aspect of thinking and cognition (Fernald and Fernald 2007).

As referred to above, epigenetic mechanisms of gene expression were crucial in the development of language. Indeed, among all organisms, epigenetic mechanisms of gene expression play the greatest role in development in humans, and among all the organs in the human body, epigenetic mechanisms play the greatest role in the development of the brain (Peedicayil 2002). Moreover, there are abnormalities involving speech and language in psychiatric disorders like autism spectrum disorders and schizophrenia (Sadock et al. 2015), and there is a category of psychiatric disorders named language disorders. Language disorders present with difficulties in the acquisition and use of language across many modalities, including spoken and written, due to deficits in comprehension or production based on both expressive and receptive skills (Sadock et al. 2015).

Human beings are the quintessential social animal, and it is language that binds human beings together in any society. In this context, psychiatric disorders are well known to be influenced by psychosocial factors in their pathogenesis (Peedicayil 2004), and psychotherapy is a key component in the prevention and treatment of psychiatric disorders (Sadock et al. 2015). Moreover, it is known that psychosocial factors act by modifying epigenetic mechanisms of gene expression in the brain during the pathogenesis of psychiatric disorders (Peedicayil 2008), and epigenetic mechanisms of gene expression are thought to be the link between psychosocial factors and psychiatric disorders (Peedicayil 2015). There is also increasing evidence that psychotherapy exerts its therapeutic effect in patients with psychiatric disorders by modifying epigenetic mechanisms of gene expression (Peedicayil

2012). Thus, psychotherapy is thought to act by “undoing” what psychosocial factors have done during the pathogenesis of psychiatric disorders (Peedicayil 2017).

As discussed above, cultural inheritance is thought to underlie normal behavior and psychiatric disorders. As also discussed above, epigenetic mechanisms of gene expression were the link in the transition from genetic inheritance to cultural inheritance during the evolution of heredity. Hence, one can infer that epigenetic mechanisms are likely to play a major and crucial role in the pathogenesis of psychiatric disorders. Indeed, this is proving to be the case: there is increasing evidence that abnormalities of epigenetic mechanisms of gene expression underlie psychiatric disorders (Lee and Avramopoulos 2014).

Conclusion

Cultural inheritance is found in many animal species. However, it has only markedly evolved in humans. In humans, cultural inheritance underlies normal behavior as well as psychiatric disorders. Since cultural inheritance evolved from genetic inheritance by changes in epigenetic mechanisms of gene expression, epigenetic mechanisms also underlie normal behavior. Abnormalities of epigenetic mechanisms of gene expression predispose to psychiatric disorders.

Florida International University, Miami, FL, USA

Synonyms

Cultural quotient (CQ); Culture and intelligence

Definition

Cultural intelligence is understood as the capability to relate and work effectively across cultures.

Introduction

The initial proposal about cultural intelligence was presented by Earley (2002). Cultural intelligence has been defined as the individual's capacity to function and manage effectively in culturally diverse settings (Ng 2013). A concise definition of cultural intelligence was proposed by Thomas et al. (2008) as a system of interacting abilities that describe how these elements interact to produce culturally intelligent behavior and then identify measurement implications.

It can be hypothesized that from early in life, humans possess strong abilities for sociocultural

cognition; these abilities represent a framework for the further development of complex cognition. This is precisely the hypothesis known as cultural intelligence hypothesis (Herrmann et al. 2007).

Cultural Intelligence Characteristics

Cultural intelligence, sometimes referred as cultural quotient (CQ), is measured in a similar way to that used to measure the intelligence quotient (IQ) in general intelligence tests. People having a higher CQ are considered more successful when dealing with any cultural environment.

A cultural intelligence model composed by different dimensions has been developed (Earley and Ang 2003). According to this model, four different cultural intelligence dimensions (metacognitive, cognitive, motivational, and behavioral) and three intercultural effectiveness outcomes (cultural judgment and decision-making, cultural adaptation, and task performance in culturally diverse settings) can be distinguished. Diverse studies have demonstrated a consistent pattern of relationships where metacognitive cultural intelligence and cognitive cultural intelligence can predict cultural judgment and decision-making; while motivational cultural intelligence and behavioral cultural intelligence predict cultural adaptation, ultimately, metacognitive cultural intelligence and behavioral cultural intelligence predict task performance (Ang et al. 2007).

Furthermore, some relationships between cultural intelligence and personality have been demonstrated (McCrae et al. 1998). Using the Big Five personality model (Norman 1963), there have been significant associations between (a) conscientiousness and metacognitive cultural intelligence, (b) agreeableness and emotional stability with behavioral cultural intelligence, (c) extraversion with cognitive, motivational, and behavioral cultural intelligence, and (d) openness with all four factors of cultural intelligence. Therefore, the major and most important personality trait in cultural intelligence is openness to experience – a crucial personality characteristic that is related to a person's

capability to function effectively in diverse cultural settings (Ang et al. 2006).

Street et al. (2017) analyzed the question why primates vary in how much they use social learning. They found that both cerebral expansion and high reliance on culturally transmitted behavior coevolved with sociality and extended lifespan in primates. This coevolution is congruent with the hypothesis that the evolution of large brains, sociality, and long lifespans has increased reliance on culture and reliance on culture implies further increases in brain volume, cognitive skills, and longer lifespan in some primate groups.

Conclusion

Since the introduction of the concept of cultural intelligence in 2002, a significant amount of research has been developed concerning its measurement, definition, association with personality traits, and predictive capability. Furthermore, it has been observed that the evolution of larger brains and sociability is correlated with increased reliance on culture.

The concept of cultural intelligence has become an important concept in contemporary anthropology and psychology.

Cultural Transmission

Mitchell B. Whitaker
Baker College, Cadillac, MI, USA

Synonyms

Cultural evolution; Cultural learning; Social learning

Definition

The transmission of preferences, ideas, beliefs, and norms of behavior as a result of an interaction between biological predispositions and social interaction between and within generations.

Introduction

In his landmark work, *The Selfish Gene*, biologist Richard Dawkins describes living things as “survival machines” that do the work of our inherited genetic material (Dawkins 2006). Under this concept, these survival machines simply seek to survive and reproduce, a process that leads to the primary motivations of all living things, human, or otherwise.

If we are, as Dawkins says, merely survival machines for our genetic material, it suggests that we are not unique in any real way. However, that seems not to be the case, an admission that Dawkins makes freely. For Dawkins, “most of what is unusual about man can be summed up in one word: culture” (Dawkins 2006, p. 189).

Description

From a sociological perspective, culture is the language, beliefs, values, norms, behaviors, and even material objects that characterize a group (Henslin 2015). Cultural transmission occurs when those elements of culture are passed from one generation to the next. On its surface, it would appear that culture works independently of biological evolution but in a very similar format. However, this dualistic view represents a pre-modern approach to biology – an approach whose intellectual integrity has since been compromised (Cosmides and Tooby 1992). In fact, research has uncovered a symbiotic relationship between genes and culture (Bolwes and Gintis 2004; Gintis et al. 2008; Wind 1990), suggesting that culture and evolution work in concert to produce an interaction that determines either cultural or biological evolution or both (Bisin and Verdier 2005; Dick 2007; Jacobson 2009).

Where Dawkins speaks of culture as a uniquely human enterprise, others have found that it exists in chimpanzees (Whiten et al. 1999) with cultural transmission serving as a fundamental, albeit primitive, element of chimpanzee life. This suggests that the concept of culture is older than humans themselves – a concept that makes culture, or our ability to perpetuate it, of genetic origin.

Despite differences in complexity, culture in humans and chimpanzees works in a similar manner.

Darwinism holds that genes are self-replicating units that transmit biological data from one generation to the next. This is the bedrock of biological evolution. It can be seen as analogous to the hardware of a computer. But a computer requires software to run, software that requires updating from time to time throughout the life of the unit itself. Culture is that software and its basic unit of transmission is the meme, a term coined by Dawkins himself. Much like the gene, the meme is self-replicating, autonomous, and lacks foresight. The meme is tricky, however. It does not replicate well (low fidelity), like genes do, and is difficult to track, leading some to disregard the

concept altogether. It's important to understand that memes are a paradigm through which to understand the concept of cultural transmission.

Critics of evolutionary psychology often point to cultural adaptation and differences within cultures and between individuals as evidence that culture is not a biological universal, nor is it an adaptive trait. From early iterations such as Murdock (1932) to more recent arguments such as that of Lewontin et al. (1984) and Wood and Eagly (2002), critics often fail to recognize the symbiotic relationship between genetics and the environment in which they operate.

As humans we are born with a set of genetic material contributed by our parents. This material stays with us throughout our lives and determines a good deal of what we become, but it does not and cannot do it alone. Cultural transmission occurs when a social unit of replication (meme) is conveyed to us by someone. Historically, those transmitters were family and close friends, members of a group, tribe, community, etc. Sociologists call these conveyors our agents of socialization (Henslin 2015). With increased globalization, our world has gotten smaller, and our pool of transmitters has gotten much larger. As such, the memetic selection pressures are much different than they were even 25 years ago.

Conclusion

Cultural transmission is responsible for variations in language, diet, political ideology, social norms, fashion, and even part of our idea of what's attractive, offensive, or acceptable. In some extreme cases, cultural transmission can create ideologies that are difficult to alter, such as racism, religious beliefs, and political ideologies.

Definition

Cultural universals are element, patterns, characteristics, or institution that are found in all human cultures worldwide.

Introduction

The idea that there are cultural universals has existed for a long time in anthropology and can be found in some classical anthropology literature, including authors such as Durkheim, Murdock, and Lévi-Strauss, and an idea that was further developed during the mid- and late twentieth century.

Several authors have referred to diverse cultural universals. However, the most influential and best-known proposal is Brown's proposal initially presented in 1991 and again later in 2000 and 2004. Brown refers to human universals as those features of culture, society, language, behavior, and psyche for which there are no known exception and are found worldwide in every cultural group. He presents a list of hundreds of universals divided in several groups, including language and cognition (for instance, color terms for black and white, antonyms, baby talk), society (such as, kin groups, cooperation, division of labor), beliefs (including, beliefs about death, belief in supernatural, beliefs about fortune and misfortune), and technology (such as, tool making, fire, weapons) (the complete list of the universals proposed by Brown can be found in Pinker's (2002) link

included in its reference). It can be assumed that those features, traits, and behaviors found in every human group represent fundamental evolutionary adaptations and have a significant survival value.

In his 2004 paper, Brown points out that in **cultural** realm, human universals include legends, myths, daily routines, rules, concepts of luck and precedent, body adornment, and the use and development of instruments. Furthermore, in the areas of **language**, universals include grammar, phonemes, polysemy, metonymy, antonyms, and an inverse ratio between the frequency of use and the length of words. Moreover, in the **social** dominion, universals include a division of labor, social groups, age grading, family, kinship systems, ethnocentrism, play, exchange, cooperation, and reciprocity. While in the **behavioral** realm, universals include aggression, gestures, gossip, and facial expressions; in the area of the **mind**, universals include emotions, dichotomous thinking, wariness around or fear of snakes, empathy, and psychological defense mechanisms. However, there are many universals that cannot be easily classified in one or another of these areas. For instance, kinship terminologies can be simultaneously interpreted as social, cultural, and linguistic. The concept of property is both cultural and social, where taking turns speaking in conversation is simultaneously linguistic, social, and behavioral.

It can be conjecture that diverse behavioral universals quite probably have distinctive, even specific, neural substrate, and consequently are also universals of mind.

Some anthropologists, however, have questioned the existence of cultural universals, taking a cultural relativist perspective. According to this perspective, behaviors and beliefs should be understood in relation to the individual's own culture, instead of being compared with other people's criteria. Some researchers consider that there are significant differences in perceiving and reasoning abilities among different cultural group; for instance, when comparing Asians and Westerners (Nisbett 2003), differences in reasoning strategies can be found. Other researchers insist that, regardless of apparent differences among different cultures, there are robust underlying

cross-cultural universals, observed in different areas, for example, classification systems (Atran 1998), color perception (Berlin and Kay 1969), and even basic emotions (Wierzbicka 1999).

Cultural Universals Characteristics

Proposals of cultural universals have been studied from different perspectives, in different areas, and including diverse research procedures. This is a research topic that has attracted attention not only in anthropology but also in psychology, sociology, linguistics, and other research areas.

Some universals in perception, classification systems, emotional terms, and the use of some specific terms will be examined below. Cross-cultural similarities in the way perceptual experience is conceptualized have been suggested. Vocabulary in each language represents the fundamental conceptualization system, and hence, not only differences but also similarities in word categorization should be recognized.

Kay et al. (1991) analyzed data from 111 languages in the World Color Survey and confirmed the main lines of the original Berlin and Kay hypothesis (1969, 1991), which assumes that there are semantic universals in basic color vocabulary. This analysis demonstrated that visual physiology plays a role in the evolutionary development of basic color lexicon, constraining the possible composite categories to a small number of those theoretically possible. One composite category, yellow/green, is clearly attested in the data, but the sequence leading to its emergence is not clear. Colors appear in language following a specific sequence, but the two universal colors found in every language are white and black (so-called achromatic colors).

Similarities in biological classification systems have attracted special attention. It has been observed that all cultural groups think about living elements – plants and animals – in highly structure ways (Atran 1998). Folk taxonomies are developed across cultures; these taxonomies are usually different, but they also present important

similarities. It may be assumed that such taxonomies are the results of human thinking strategies. Hence, similarities in classifications systems found when comparing different human groups are reflecting human basic cognitive schemas.

Other quite different types of universals have been pointed out. For example, frequently it has been assumed that there are universal emotions and in all the languages certain emotions are distinguished (Wierzbicka 1999). As an illustration, similarities in emotional terms across languages have been proposed. For instance, Romney, Moore, and Rusch (1997) analyzed the semantic structure of 15 emotion words for monolingual English-speaking and monolingual and bilingual Japanese subjects. A major question in this study was to contrast a single shared emotion model for English and Japanese versus culture-specific models for each language. Results supported a shared model for the semantic structure of emotion terms; nonetheless, some important differences were also found between English and Japanese structures. Interesting to note, the Japanese bilingual participants used a model more similar to English when performing tasks in English than when performing the same task in Japanese.

Cordaro et al. (2018) used a Facial Action Coding System coded over 2600 free-response facial and body displays of 22 emotions in China, India, Japan, Korea, and the United States to test five different hypotheses about the universality and cultural variations in emotional expression. The authors were able to identify cross-culturally some *core patterns* of expressive behaviors for each of the 22 emotions. They also demonstrated systematic *cultural variations* of expressive behaviors for each cultural group. These variations were shaped by the cultural resemblance in values. It was concluded that there are universal core patterns, and also variations on emotional expression in each of the studied cultural groups.

Scherer and Fontaine (2019) observe that the Component Process Model of Emotions claims that the different components included in the

emotion (i.e., action tendencies, physiological reactions, expressions, and feeling experiences) are basically the results of cognitive appraisals. The authors performed a secondary analysis of the large-scale data set with ratings of affective features covering all components of the emotion process for 24 emotion words in 27 countries. Profiles of emotion-specific appraisals, action tendencies, physiological reactions, expressions, and feeling experiences were constructed. The results of a series of hierarchical regression analyses to examine the prediction of the theoretical model are consistent with the assumption that appraisal patterns determine the structure of the response components, which in turn predict central dimensions of the feeling component.

Expression of gratitude is a special type of affective and linguistic behavior that has attracted special attention in the analysis of the cultural universals. Floyd et al. (2018) point out that gratitude has evolved to motivate and maintain social reciprocity among people. Gratitude is linked with diverse positive effects from different perspectives, including social, psychological, and even physical consequences. Current studies usually do not include cross-cultural elements of gratitude and have tended to consider gratitude as an emotion associated with a linguistic practice, as in English and other Indo-European languages. Floyd et al. raised the question, to what extent people express gratitude in different societies, by focusing on episodes of everyday life where someone seeks and obtains a good, service, or support from another. These episodes were compared across eight different languages from five continents. It was found that expressions of gratitude in these episodes are quite unusual, suggesting that social reciprocity in everyday life activities are based on implicit comprehension of rights and duties surrounding reciprocal collaboration. It also was observed in minor cross-cultural variations, with relatively higher rates gratitude expressions in Western European languages – English and Italian. Noteworthy, some Amerindian languages have few, if any, gratitude words, equivalent to “thank you.” For instance,

Guarani and Aymara languages use Spanish borrowings for “thank you”: *agradese* (from Spanish, *agradecer*, to thank) is used in Guarani language (spoken specially in Paraguay but also in Argentina, Bolivia, and Brazil); “thank you” in Aymara language (spoken specially in Bolivia, but also in Peru and Chile) is *yuspagará*, an adaptation of the Spanish expression *Dios pagará*, meaning “God will pay.” The expression “thank you” in many languages means “I give you my benefits”; for instance, in Spanish *gracia* from the Latin *gratia* means “grace,” and “charm.” In Russian, “thank you” can be *spasibo* (спасибо) but also *blagodaryu* (благодарю) which means “I give you the good.”

Naito and Washizu (2015) analyzed gratitude from an East Asian perspective. They conclude that the concept of gratitude has been studied under the universality hypotheses, which postulates the following: (a) gratitude is influenced by its antecedent factors, including gains of the beneficiary, cost to the benefactor, and the altruistic motivation of the benefactor; (b) gratitude implies positive feelings, such as attachment and respect for the benefactor and the wish to repay the benefactor; (c) gratitude may lead to particular behaviors such as expressions of the gratitude directed at the benefactor, repayments, and pro-social behaviors directed at other people in general; and (d) experience of gratitude is associated with positive attributes, such as well-being. But gratitude has many nuances, depending upon the language and the cultural context.

Universals in language have represented a major topic of analysis, as observed in Brown’s (1991, 2000, 2004) list of cultural universals. Universals in language during language development can also be conjectured. Ochs (1991) proposed that indeed there are cultural universals in the acquisition of language. He further proposed a model according to which (1) there are culturally universal trends in the linguistic marking of four language dimensions (epistemic and affective stances, social acts, social activities, and social identity); (2) language and culture universals basically consist in the “indexing” of stance and social

acts, the marking of which is more extended and conventionalized across social groups than the marking of other domains; and, finally, (3) language and culture particulars refer primarily to how stance and social acts are related to social activities and social identities. This model clearly recognizes that the universals in language can be observed not only in adult language but also during language development.

Conclusion

Since the earlier twentieth century, the idea that there are cultural universals has existed, meaning, elements, patterns, characteristics, or institution found in all human cultures worldwide. This is an idea that has become quite influential not only in anthropology but also in other scientific areas, such as psychology, sociology, and linguistics. Extensive lists of universals including hundreds of different elements have been proposed. Cultural universal cover different areas, including but not limited to language, social life, and cognition. However, some disagreement persists. Special interest has had the analysis of the cultural universal in classification/conceptualization systems, perception, emotions, and language.

Definition

The examination of differences in human behavior and development across contexts and cultures is crucial in appreciating human diversity.

Introduction

Although cultural universals are widely critiqued for the lack of emphasis on the diversity of human experiences and its Eurocentric principles (Ziai 2019), an examination of both variations and universals among cultures has been foundational in ethnography. Cultural universals are defined as similarities between human traits and attributes across cultures (Norenzayan and Heine 2005). For example, expressions of some emotions such as happiness, sadness, disgust, fear, surprise and anger (Ekman and Friesen 1971), sympathetic impartiality and communication (Wiredu 1995), arts, recreation, and social and economic organization (Cleaveland et al. 1979) appear to exemplify such universals.

Cultural variations, on the other hand, integrate diversity in development, behavior, and expectations across cultures as a result of human adaptation to their environment (Cohen 2001). Ethnographers, in their attempts to qualify cultural variations, have identified 30 dimensions. Examples of some of these dimensions are *contact vs. no-contact cultures*, *universalism vs. particularism*, *individualism vs. collectivism*, and more (Triandis 1982) and have concluded that cultural variations are an inevitable part of human life.

To illustrate, Ekman et al. (1987) reported that despite the universality of emotions, there are significant cultural variations in the intensity ratings of emotional expressions of happiness, surprise, and fear between Asian and non-Asian cultures. Asians tended to rate facial expressions to be of lower intensity, and the differences were particularly prominent in the ratings of fear. Ekman et al. applied Matsumoto's (1989) ideology and explained the pretext for lower ratings. Matsumoto suggested that decoding rules vary between individualist and collectivist cultures. Since, in collectivist cultures, negative emotions can be a threat to

group dynamics and cohesion, they are often downplayed. The justification provided by Matsumoto thus provides supporting groundwork to Cohen's explanation of cultural variations being adaptive and functional, thereby creating a sense of equilibrium within the members.

Functional Aspects of Cultural Variation

Hassan et al. (2019) advocated for the appreciation of "context-specific factors" (p. 11) while interpreting differences in the investment of mothers and fathers in their sons and daughters. In the Tanzanian sample of parents with children under the age of 5, Hassan et al. found that fathers discriminated among their children and favored sons over daughters, whereas mothers did not discriminate and invested equally regardless of their children's sex.

Abiding with the ideas of Cohen (2001) on the functional aspects of cultural behaviors, Hassan et al. (2019) asserted that Tanzania, being a patrilineal and patrilocal society, favors men over women. Thus, fathers are more likely to benefit from their sons as they will inherit the family property and continue the family name and legacy. Daughters, on the other hand, will be married and leave their parents' household, and therefore favoring them is not cost-effective. In contrast, mothers do not discriminate and favor both sexes because of obvious payoffs from sons and household chores and childcare help from daughters.

Cultural Variations and Implications for Research and Practice

Legare (2017, p. 429) suggested that most of the psychological research consists of "WEIRD" (Western, educated, industrialized, rich, democratic) participants resulting in a myopic view. As established above, cultural variation is adaptive and serves essential functions in a society and maintains equilibrium among its members. Moreover, cultures influence human development and behavior and their manifestations, motivations, directions, and constraints. Therefore, the

examination of the multidimensional aspects of cultural variation and its pretext is mandated to understand human diversity in all its forms. Although the influence of cultures on socialization, care, values, and beliefs is partially studied, cross-comparison investigations need to be further strengthened. The research can be strengthened through the development of culturally appropriate, valid, and sensitive screening and diagnostic measurement tools (Carlo and Maiya 2020) and designing culturally sensitive intervention programs.

Conclusion

Cultural variations are an integral part of human life, and therefore integrating cultural aspects in research will prompt us to ask more relevant and valuable questions and get meaningful information. The empirical evidence thus gathered can assist in designing and implementing culturally sensitive interventions (McClain et al. 2019).

Culture of Honor

Victor N. Keller
Michigan State University, East Lansing, MI,
USA

Synonyms

Aggression; Collectivism; Dominance; Face; Masculinity; Pride; Reputation; Respect; Violence

Definition

Honor commonly refers to how others see an individual (usually a man) in terms of his respect, pride, dominance, and/or masculinity. Cultures of honor are those in which individuals strive to maintain their honor.

Introduction

The presence of a culture of honor is commonly used to explain differences in aggressive behavior of men from different regions, countries, or societies. The most prominent example of these differences comes from the pioneering research program by Richard Nisbett and Dov Cohen (1996). They compared male aggressive behavior in different US regions and consistently found that when the honor of men from the South was challenged they were more aggressive than were men from other regions (primarily the North). Similar results have been found in multiple other countries using many different measures of emotion, cognition, and behavior (for a brief review see Rodriguez Mosquera 2013).

However, men from cultures of honor are not found to be more aggressive in all situations, only in those in which their dominance or masculinity is challenged by another individual. For example, Cohen et al. (1996) had an actor physically bump into and insult a participant while observers assessed the participant's reaction. Those from a

culture of honor (Southern USA) reported feeling that their masculine reputation was more threatened, had higher levels of testosterone and cortisol, and responded more aggressively than individuals who were not from a culture of honor (Northern USA). Furthermore, men from cultures of honor have been shown to react more aggressively to a romantic partner's sexual infidelity (by attacking their partner or the other man) and sexual promiscuity of women in their family (Rodriguez Mosquera 2013). There are many explanations for why these situations evoke such responses from men in cultures of honor; three of them are outlined below.

Explanations for the Culture of Honor

One of the first explanations for societal differences in culture of honor was proposed by Cohen et al. (1996). They argued that the development of a culture of honor was associated with herding economies. In regions where herding was the main means of sustenance, there usually lacked governmental oversight, and an individual's resources could easily be robbed with little to no punishment. These circumstances increased the value of having a reputation for being dominant. Men who allowed others to publically insult them or otherwise question their dominance would be viewed as weak and more likely to become targets of theft. Those who were known to be dominant and able to protect their livestock were less likely to be victims of theft. Thus, a culture of demonstrating dominance and maintaining one's honor would develop as a means of protecting one's property. Furthermore, such a culture would be transmitted from generation to generation perpetuating its violent retaliatory practices, even after the advent of governmental authorities.

A different explanation for why cultures of honor develop was proposed by Thornhill and Fincher (2011). They argue that a culture of honor is more likely to develop in regions where there is a higher likelihood of contracting infectious diseases from other individuals. Because life-threatening parasites are more likely to come from individuals outside one's group, increased

parasite stress leads to an increase in collectivistic values, such as strong loyalty to the in-group (e.g., family), a sharp boundary with the outgroup, and respect for hierarchies. These collectivistic values in turn foster stronger reactions (e.g., honor killings) to offenses to one's family or challenges to one's dominance. To substantiate their explanation, Thornhill and Fincher (2011) analyze US-state level data on parasite stress, collectivism, and interpersonal violence. They find that states with higher levels of parasite stress have more cases of male-to-male and male-to-female violence associated with maintaining honor.

Shackelford (2005) offers yet another explanation for the development of cultures of honor. He argues that the violent behavior of honor cultures serves the evolutionary goal of retaining one's mate. Demonstrating aggression towards other males that might attempt to steal one's mate and discouraging one's mate from having sexual relations with other men decrease the odds that one's mate will court other males. Shackelford (2005) proposes that regional differences in honor aggression might be due to differences in the likelihood of mate infidelity – a topic for future research.

Conclusion

The explanations offered here do not exhaust the possible explanations for cultures of honor and they are by no means mutually exclusive. Cultures of honor may develop due to more than one reason, and different reasons may explain cultures of honor in different countries. Future research may shed light on the nuances of different cultures of honor and propose means of addressing the societal problems that are associated with them.

Synonyms

Aggression; Masculinity; Phenotypic variance

Definition

Within culture individual level differences on reactions against threats to reputation.

Culture of honor has been defined as a specific cultural context in which individuals – predominantly males – react against threats to their reputation. Those reactions are in general aggressive and violent even if they are risky and costly (e.g., life-threatening) to oneself (Nisbett and Cohen 1996). Individuals in honor cultures prioritize their reputation against their safety and/or material gains. Even though it seems costly in the short run, individuals in honor cultures protect and preserve their self-worth in this way. In conflictual situations, individuals might deploy an “interest strategy” by avoiding risks or “rational strategy” by being aggressive when in an advantaged condition yet surrender when in a disadvantaged condition. As another option, individuals in honor cultures use “honor strategy” by striking back regardless of their current condition in that conflictual situation (Nowak et al. 2016).

Cross-cultural research on honor provides evidence for cultures as Mediterranean culture and southern states of United States valuing honor. There are also research aiming to explore the mechanism behind honor culture. For instance, low reliability of institutions, the toughness of the environment, herding cultures, and low-status compensation (e.g., Henry 2009) have been linked to honor cultures. Besides the research focusing on evolutionary and sociocultural correlates, a body of research has focused on the relationship between the culture of honor and individual differences.

Saucier and McManus (2014) argue that there is an individual difference in masculine honor beliefs regardless of the culture where individuals grew up. For instance, females scored higher on family and community masculine honor, while males scored higher on all other dimensions including courage, pride, virtue, protection, and provocation. Furthermore, individuals who scored higher on masculine honor beliefs also scored higher on trait aggression and benevolent sexism. For instance, it was found that masculine honor beliefs are associated with participation and action in sports such that

individuals with higher masculine beliefs prefer sports requiring physical contact (Saucier et al. 2016).

Furthermore, higher scores on honor values are correlated with rationalization and reinforcement of confrontational behavior against a hypothetical false accusation and disrespect (Cross et al. 2013). Likewise, individuals of honor culture are more sensitive to insults, immediately prepared for retaliation both physiologically and cognitively, and, as a result, more likely to express aggressive behaviors (Cohen et al. 1996). Regarding the close relationships, individuals who value honor favor loyalty of females and justify domestic violence by males (Vandello et al. 2009). Similarly, Vandello and Cohen (2003) found that individuals from honor culture perceive female infidelity as a threat to one's reputation and justify domestic violence and anticipate loyalty of females even if they are the target of domestic violence as a result of jealousy. Cohen and Nisbett (1997) also showed that honor culture is related to sympathetic reactions to violence as stabbing someone in response to family insult.

Thus, for individuals with high honor values, self-worth and social status are especially important. Moreover, research on individual differences yielded that honor is not only associated with protecting self-worth and social status, but it is also highly relevant for moral behavior (Cross et al. 2014). One study investigating individual differences on this topic revealed that higher endorsement of honor ideology predicted practice of extreme counterterrorism tactics above and beyond the right-wing authoritarianism and social dominance orientation (Barnes et al. 2012).

Culture of honor studies heavily focuses on culture differences. However, culture of honor beliefs and related behaviors such as aggression also shows individual differences. Therefore, it is also important to consider within-culture variation and individual differences to extend our understanding of culture of honor.

Definition

Cultures of honor are those placing a high emphasis on the importance of a man as willing and able to violently and lethally retaliate against anyone who insults his honor or the honor of his family. Thus, the defense of personal and family honor results in the favoring of kin for economic and socially valuable positions.

Introduction

The label “cultures of honor” refers to cultures placing a high emphasis on the importance of a man’s willingness and ability to violently and, even lethally, retaliate against anyone who insults his honor or the honor of his family. These insults typically involve accusations that a man’s male kin are cowards or that his female kin, wife, or female in-laws are not chaste. Such accusations may lead to the killing of the accuser and/or the killing of the accused female by her male kin, husband, or in-laws. These behaviors appear to be extreme forms of universal evolved aspects of human behavior. Thus, there has been an attempt to identify what social and ecological aspects of the environment may tend to produce these extreme forms (Shackelford 2005). The most well known of these studies was conducted by

Nisbett and Cohen (1996) on the US South; in it, the authors suggest that weak/ineffectual authority and the potential for complete theft of a man's livelihood (specifically livestock) lead to a culture of honor where violent, even lethal, retaliation is commonplace.

Key Factors in the Creation of Cultures of Honor

In addition to kin selection, the aspects of evolved human nature apparently contributing the most directly to cultures of honor are parental-investment theory, male sexual jealousy, and reputation management. Parental-investment theory holds that greater variance in male reproduction leads to males tending to pursue a life history of high mating effort that often includes high cost forms of violent competition with other males (Trivers 1972). The diversion of some of this mating effort to parenting effort is only evolutionarily advantageous when paternity certainty is sufficiently high, leading to selection of various forms of mate guarding and male sexual jealousy (Daly and Wilson 1988). In addition to evidence of infidelity being often followed by a lessening or termination of paternal investment, violence is often exhibited toward the mate. In addition to potentially deterring the female from infidelity, violent sexual jealousy can also influence other females who are potential mates and other males who may be deterred from pursuing sex with the man's mate or mates. These signals are part of the man's reputation management. Reputation management involves the influence of one's behavior on individuals who are not directly involved in that behavior, but are nonetheless influenced by it indirectly through observing the behavior or hearing about it. This is usually applied to indirect reciprocal altruism where an individual benefits from their altruistic acts because these acts are reciprocated, not by the recipient but by onlookers and/or those becoming aware of the individual's reputation for being an altruist. However, a reputation for many behaviors other than altruism can be created in the same way, and these reputations may also have significant evolutionary

consequences (Alexander 1987). Namely, solidarity with one's kin, through nepotism, creates an environment where honor can be defended by a coalition, and family reputation can be cultivated. Where men are isolated from kin, they lack the backing of a coalition for defending their honor, and lethal violence becomes much riskier.

All of these factors also influence the fitness of kin because kin selection predicts that individuals should value the behavior of their kin in accordance with Hamilton's rule (Hamilton 1964). This is most commonly applied to acts of altruism toward kin, but shared genetic makeup of close kin produces a more general common interest among close kin where not just altruism but behavior in general by one will have consequences for the other. Cultures of honor have been hypothesized to occur when the evolutionary concepts just described interact and take on an extreme form (Shackelford 2005). This extreme form is identified by high levels of violence toward both the impugner and the accused, especially the female kin accused of sexual impropriety. This in turn often leads to retaliation and the development of blood feuds.

US South

Although all of the factors that contribute to a culture of honor may be universal aspects of evolved human nature, they appear to be emphasized more in some cultures than others. Thus, hypotheses have attempted to account for this variation. Addressing the culture of violence in the US South, Nisbett and Cohen (1996) proposed that it was agropastoral environments (and heritage) combined with a weak governing body that produce cultures of violence due to the possibility of the complete theft of a man's livelihood and little recourse to authority. They supported this view with a series of experiments that compared men in the Southern United States (which was settled primarily by herdsmen from Ireland and Scotland), with men from the Northern United States (settled primarily by farmers from England). The factors contributing to an extreme culture of honor in such an environment are the

relative absence of external law enforcement and punishment, and easily stolen forms of wealth (Shackelford 2005).

Chu et al. (2000) conducted an independent analysis of the available data and found that after controlling for environmental variables, and then for poverty, there was either no relationship or one opposed to that found by Nisbett and Cohen (1996). Chu et al. did make an important distinction in their study: they separated the connection of herding-based societies producing cultures of honor from the connection of violence with cultures of honor. The two are not necessarily linked, and thus their analysis could be seen not as a rebuttal of Nisbett and Cohen, but as a refinement.

Other Cultures of Honor

Data on cultures of honor from other cultures around the world is largely limited to North Africa and Southern and Southwestern Asia. Here, cultures of honor are characterized by a quick recourse to violence, usually due to an insult of family honor or accusations that a female relation is not honorable/chaste/faithful. Honor killings of women are a relatively common occurrence in these cultures of honor. They appear to be closely related to nepotism and kin selection because they are commonly perpetrated by brothers and mothers of the accused (Kulczycki and Windle 2011). The circumstances that are present in this part of the world are highly variable, from nomadic herders to urban laborers, and thus do not always agree with what Nisbett and Cohen proposed for the US South. For example, Moritz (2008) argues that the various pastoralist cultures in Africa encompass substantial environmental and social differences and cannot be considered under a single analytical label. Further, similarly to Chu et al. (2000), Moritz argues that the “honor psychology” and “pastoral personality” (p. 100) are distinct categories that may overlap, but do not necessarily do so. This complicates the connection of cultures of honor and nepotism; connections beyond simple coalitional defense of reputation are unlikely to be the result of any single factor, but of some collection of possible

factors, interacting within different environments, that give rise to cultures of honor.

The current literature on honor killings is largely framed as violence against women or as a function of political economy/power, and thus further study is necessary to illuminate the specific evolutionary aspects of these cultures of honor. However, the simple fact that these cultures of honor exist in variable economic and social circumstances lends support to Shackelford’s (2005) idea that the evolved psychological mechanisms that lead to cultures of honor are not likely to be a result of relatively modern economies (i.e., herding) or lack of formal authorities but to the common problem of the theft of the reproductive value of a wife that was confronted by ancestral men (and the social consequences of this for kin).

Conclusion

Identifying the correlates of cultures of honor can have important practical implications, such as possibly identifying ways of lowering certain forms of violence. From a theoretical point of view however, cultures of honor develop not as an adaptation that has evolved in some human populations but not in others, but as one outcome of selection for a number of universal human adaptations found in all humans. This is because the specific environmental factors involved in the agropastoralism proposed to produce extreme cultures of honor are too recent to be an adaptation, and are thus best considered a by-product of a novel environment.

The nepotism that is associated with cultures of honor is a function of kin selection and reputation management and serves to create an environment where men have a ready coalition (especially in positions of power) that can be called upon to defend their personal and familial honor. Thus, one would expect increased nepotism in places where coalitions were/are necessary to defend one’s honorable reputation (perhaps due to weak/ineffective external authority) such as the US South and parts of Africa and Southern and Southwestern Asia. Although many aspects of cultures of honor involve kin who are so close

that kin selection may have been involved in their evolution, often the imperative to defend the honor of one's kin applies to one's very distantly related clan members. That is, one is expected to avenge an insult to individuals identified as kin by the inheritance of a traditional descent name inherited from a long-dead common ancestor. The inclusion of very distantly related kin among the individuals one is expected to avenge in some cultures of honor is an area in need of further study.

Finally, the vast majority of the literature focuses on men and male actions in creating and perpetuating cultures of honor and acts of nepotism. However, it is unlikely that the other half of the population, women, is uninvolved or oblivious to personal and familial honor, and the violent defense thereof. Whether women act as cultural repositories and serve to socialize their sons into cultures of honor (Nisbett and Cohen 1996) or if they take a more active role is an area that requires extensive study.

Culture of Honor and Retaliation

Definition

Cultures of honor are cultures in which the concept of honor is thought to play an important role in everyday life. Retaliation is an action undertaken to harm someone else who has harmed oneself.

Introduction

“Culture of honor” is a label scientists from various disciplines (psychology, anthropology, sociology) use for cultures in which the concept of honor governs everyday behavior. These cultures can be found in the Mediterranean area (Spain, Turkey, Syria, Egypt), the Arabic peninsula, Central Asia (Afghanistan, India), the South of the United States, and in gang life (Horowitz and Schwartz 1974). Honor cultures are thought to arise when groups settle in harsh environments, lacking sufficient resources and law enforcement (Brown and Osterman 2012; Nisbett and Cohen 1996; Nowak et al. 2016; Shackelford 2005). As a consequence, honor codes – rules on appropriate

conduct (Stewart 1994) – start to govern social behavior. For example, it is thought that the culture of honor in the South of the United States is a remnant of the herding population that originally inhabited the Southern states (Henry 2009). Herding life relies on the ability to protect oneself and one's property from external threats. Responding violently to threats is then an adaptive strategy. Also in other honor cultures, for instance in Turkey, herders seem to be more sensitive to threats than farmers (Uskul and Over 2014). Even though harsh and lawless environments have largely disappeared in regions described as honor cultures, norms regarding violence seem to perpetuate. In the South of the United States, this seems to be the case due to pluralistic ignorance: Individuals falsely assume others to endorse norms in favor of violence and thus act accordingly themselves without personally valuing aggression (Vandello and Cohen 2004). However, pluralistic ignorance could not explain the perpetuation of positive attitudes toward violence in Western Turkey (Van Osch et al. 2013).

What Is Honor?

The multidisciplinary literature on honor has identified many differences in responses to honor threats between cultures considered high and low in honor (Uskul et al. *in press*). Most of this research is of a descriptive nature concluding that *x* is more often observed in cultures high than in cultures low in honor. Cultural differences have been documented in the extent to which people value the concept of honor (Martins Guerra et al. 2012) and how insults or affronts affect people's self-esteem (Rodriguez Mosquera et al. 2002) and emotional (Rodriguez Mosquera et al. 2008) and aggressive responses (Cohen et al. 1996; Van Osch et al. 2013). This research has provided a wealth of information on cultural differences between cultures high and low in honor, but has shed little light on the underlying psychological processes.

Here, honor is defined as a moral reputation. Honorable individuals are treated as worthy members of their community. Honor can be lost by

immoral conduct which has severe social consequences for the person and his or her associates. Humans are social beings and have a fundamental need to belong to groups (Baumeister and Leary 1995). Groups have rules that they want each group member to abide to. If members break the moral code, they are stigmatized and socially excluded (shunned, expelled). This is a functional response, because deviant behavior may threaten the survival of the group (Kurzban and Leary 2001) and responding to it strengthens the group's identity and "sense of common morality" (Jones et al. 1984). It is irrelevant whether the individual actually transgressed or is perceived as having done so, because the group will act based on their perceptions of moral deviance. The stigmatized who risk exclusion experience threats to their belonging, self-esteem, control, and meaning in life (Williams 2007) and have no choice but to defend or restore their moral reputation (Goffman 1963) in order to prevent social exclusion. Also, those who are close to the transgressor can be associated with the transgressor and suffer from a stigma by association requiring them to protect their own honor (Benavidez et al. 2016; Marques et al. 1988).

The psychological processes underlying responses to honor seem universal (Novin and Oyserman 2016; Shackelford 2005). Immoral conduct can result in stigmatization and social exclusion across cultures. What is considered immoral conduct however may differ across communities. Acts like rape, murder, or pedophilia are considered immoral almost everywhere. However, there are also acts that are considered immoral in some but not in other communities, for example, adultery (Erners 2007), premarital intercourse, or homosexuality (Matsumoto and Juang 2013). Cross-cultural differences in responses to misconduct may not only result from different perceptions of misconduct but may also result from differences in how salient the concept of honor is in a given community. Cultures high in honor, due to historical reasons (settling in harsh lawless environments), may have hypercognized the concept of honor. A psychological concept is hypercognized if it receives considerable attention, meaning that

there are many terms available to describe the concept (for instance, in Turkish there are at least four different terms available for honor; Ermers 2007), that members have a lot of explicit knowledge on the phenomenon, and that this concept is deemed important in the community (Levy 1973). Hyper-cognizing a concept does not imply differences in psychological experiences (Frijda et al. 1995; Parkinson et al. 2005) but may trigger (culture-) specific thought and action repertoires when activated, explaining why people in different cultures act in different ways when they commit or observe immoral behavior.

Threatened Honor

In line with the reasoning above, people can lose their moral, or good, reputation in roughly three ways. First, people can be the actors of immoral behavior. For example, if a Turkish woman engages in adultery, her honor is threatened. Adultery is not accepted in many communities in Turkey, and the accused will suffer the consequences. An adulterous woman is considered a bad, indecent woman and will no longer be trusted. She could be shunned or punished by her community and/or divorced by her husband (Ermers 2007).

Second, people can be associated with moral deviants. Stigmas do not only stick to the individual who misbehaved, but stigmas may transfer to those associated with that individual. This is called stigma by association or a courtesy stigma (Goffman 1963). Children can be stigmatized due to the misconduct of their parents (sex offenses) and have to deal with threats, differential treatment, and bullying (Levenson and Tewksbury 2009). Being friends with a stigmatized individual (e.g., homosexual) can already be enough of an association to suffer from a stigma by association (Neuberg et al. 1994). So, an adulterous woman in Turkey could be stigmatized and excluded herself, but also her parents, her husband, and her in-laws could become the targets of stigmatization and exclusion. They could have prevented her from misbehaving and thus can be held partly responsible for the misconduct.

Third, people's honor may be threatened because of a cowardice stigma. To prevent stigmatization and social exclusion and promote future cooperation, people should manage their reputation (consisting of both moral and nonmoral qualities such as social status) to ascertain their valued position in a community (e.g., Emler 1990). It is seen as honorable if people are willing and able to defend their reputation. If people fail to respond to messages that impact their reputation, or fail to respond strong enough, they may be seen as weak. For example, men in the South of the United States respond vehemently to insults in order to retain their reputation for toughness and protect themselves (Cohen and Nisbett 1994).

Honor and Retaliation

Retaliation is a potential reaction to all three types of honor threats. First, when the moral deviant is stigmatized, and marked as without honor, this negatively impacts someone's self-esteem (Major and O'Brien 2005). Apart from impacting one's self-esteem, being threatened with social exclusion also threatens other fundamental needs such as the need to belong and the need for control (e.g., Leary 2005; Williams 2007). Expecting or experiencing such threats can result in aggressive responses (Twenge et al. 2001; Warburton et al. 2006). Moral deviants may aggress and become vengeful toward those who confront them with their immoral behavior and thus humiliate them (Combs et al. 2010; Elison and Harter 2007).

Second, if people's honor is at stake because of their association with a moral deviant, they can aggress toward the accusers if the claim is unfounded (accusation rather than actual misconduct), or they can aggress toward the moral deviant to cleanse their own reputation. Research has shown that individuals distance themselves from deviants in order to decrease the chances of stigma by association (Eidelman and Biernat 2003) and sanction their deviant behavior (Chekroun and Nugier 2011). In more extreme cases, the moral deviant is killed. These so-called "honor killings" occur when the associates of the often sexual deviant kill

the deviant to reestablish or cleanse the honor of the group or family (Ermers 2007). In cases where sexual deviance affects the honor of a family, the family has two options. The first is to kill the man of the other family, if they consider the man “guilty” of damaging the family’s honor (for instance, in the case of rape; Ermers et al. 2010). This is considered an external settlement. The second option for the family is to kill their own relative, if the woman is held responsible for damaging her family’s honor (for instance, if she actively sought to deviate from the moral rules; Ermers 2007; Ermers et al. 2010). This type of internal settlement, and its underlying psychology, also seems to occur in Western societies in the form of violence against women by male relatives (Baker et al. 1999).

Third, if people are falsely accused of immoral behavior, they might aggress toward those who are falsely accusing them in order to prevent oneself from a cowardice stigma. Slander should be prevented, and the victims of the slander should undertake some form of action toward the source of the slander (Ermers et al. 2010). Using aggression to defend oneself can be functional as it protects resources and creates a reputation that deters future attacks (Buss and Shackelford 1997). In a recent laboratory study, it was demonstrated that Turkish students who were falsely accused of dishonesty (a moral quality) retaliated against their experimental partner, more so than students from the North of the United States (Uskul et al. 2015). Most research on the culture of honor in the South of the United States relies on this idea of a cowardice stigma, especially men protecting their reputation for toughness. Most research centers on examining differences in aggression between Southern and Northern parts of the United States. White males in the South are more prone to respond aggressively than those in the North of the United States, as evidenced in homicide rates (Messner 1983; Nisbett and Cohen 1996), school shootings (Brown et al. 2009), having people respond to offenses in experimental settings (Cohen et al. 1996), or measuring the approval of interpersonal violence for self-protection purposes (Hayes and Lee 2005; Nisbett and Cohen 1996).

A final form of retaliation, often related to honor, is called blood revenge and occurs across cultures (e.g., India, Turkey, the Middle East, Northern Africa, the Balkan Peninsula). Blood revenge is the killing of someone by others for having inflicted harm to someone from their group. For example, a man might be hurt or killed by another family because he hurt or killed someone from that family (Abu-Lughod 1985). The goal of such revenge is to reestablish a balance between two families or tribes (Ermers 2007).

Conclusion

Threats to one’s honor thus can result in retaliation. In general, people aggress toward those causing the honor threat. First, moral deviants themselves can become aggressive because of their loss of self-esteem and control. Second, those who suffer from a stigma by association may punish the person causing their stigma. Third, those whose reputation is challenged retaliate against those challengers in order to maintain their good reputation. These responses seem to occur across cultures but may be more explicit and present in communities in which the concept of honor is salient in everyday life.

Synonyms

[Oral sex](#); [Sexual intercourse](#)

Definition

Oral sex act or stimulation performed by a person on the female genitalia.

Introduction

Cunnilingus is the stimulation of the female genitals by a partner's lips or tongue. One study of heterosexual female college students indicates that approximately 67% have been on the receiving end of oral sex while 99% of those same students have performed fellatio on a male partner (Bay-Cheng and Fava 2011). This sexual behavior is not only found in humans. For example, the Indian flying fox engages in cunnilingus, and those males who perform cunnilingus before copulation engage in longer copulatory sessions with their mate (Maruthupandian and Marimuthu 2013). It is also common in a number of insects (Gregorič et al. 2016). Although it does not appear to offer *direct* genetic benefits, performing cunnilingus can be advantageous to engage in for other reasons among humans.

Evolutionary Advantages of Cunnilingus in Humans

Engaging in cunnilingus in adolescence seems to be a proxy for sexual intercourse in the future and

may provide the individual with reputational popularity, but not likability from their peers (Prinstein et al. 2003). Additionally, when couples engage in oral sex more frequently, they tend to report more relationship satisfaction (Frederick et al. 2017). Women are also more likely to have an orgasm when they receive cunnilingus (Richters et al. 2006). Aside from positive affect, performing cunnilingus can be beneficial because it can function as a way to influence one's partner.

For starters, cunnilingus can be a way to combat sperm competition. Novel research methods – found via pornography coding – suggest that there is a positive relationship between attributes of male ejaculation and time spent performing cunnilingus among pornographic actors (Pham et al. 2016). Therefore, performing cunnilingus before copulation may, in part, produce more sperm which (1) could compete with other sperm in the reproductive tract or (2) produce more sperm to fertilize the ova. Furthermore, performing cunnilingus may be a way to taste or smell rival semen (Thornhill 2006). Although there is no empirical work on this, there is evidence that men who are at greater risk of infidelity and sperm competition report spending more time performing cunnilingus (Pham and Shackelford 2013a; Pham et al. 2013).

Engaging in cunnilingus can also be used to manipulate one's partner. For example, both men and women perform oral sex on their partner as a benefit-provision mate retention behavior (Sela et al. 2015). In addition, men who perform more mate retention behaviors and more benefit-provision mate retention behaviors report a greater interest in performing cunnilingus on their partner (Pham and Shackelford 2013b) which can alter their partner's behavior and can influence their relationship satisfaction (Frederick et al. 2017).

Conclusion

Cunnilingus can be a tool to facilitate satisfaction within the relationship and can be a tool to combat

sperm competition and retain one's partner. Future research should examine how women manipulate men into performing cunnilingus and how engaging in cunnilingus similarly benefits non-heterosexual couples (e.g., used as a mate retention tool).

[Optimal foraging models; Utility](#)

Definition

In optimality modeling of behavior, “currency” is the variable the model assumes is maximized by natural selection, while “constraints” are the hypothesized environmental, cognitive, or physiological limitations that shape the animal's ability to maximize currency. The currency and constraints of a model are best considered hypotheses that establish model predictions to be tested with behavioral data.

Introduction

Optimality models of behavior aim to develop testable predictions about the behavioral decisions of organisms under the assumption that natural selection has favored behavior patterns that maximize Darwinian fitness. These models and their

predictions arise from two sets of hypotheses that are implicitly or – more helpfully – explicitly described in the model as **currencies** and **constraints**. The currency in an optimality model is the net benefit of the behavioral decision hypothesized to be closely related to the animal's Darwinian fitness. Constraints are the environmental, physiological, or cognitive features that are hypothesized to limit the animal's ability to maximize the currency (Krebs and Davies 1984). For example, in a model that predicts the optimum amount of time that a male dung fly should mate with a female, the maximized currency could be the total number of eggs fertilized by the male (a variable closely related to Darwinian fitness), and the constraints include: the amount of time it takes to find and display to each female, the relationship between time spent mating and egg fertilization, and the ability of males to assess time.

Energetic Currencies

In optimality models, the currency is a measurable variable that is hypothesized to be closely related to Darwinian fitness. Fitness is difficult to measure directly as it accumulates over the entirety of the animal's lifetime and is dependent on population structure. In models of foraging decisions (the most well-developed models in behavioral ecology), the currency most frequently hypothesized to be maximized by natural selection is some measure of the net energy gained from food items. This is a reasonable starting point since energy will be used to improve the animal's ability to survive, find mates, and reproduce.

There are two major categories of energy currency typically used in optimal foraging models: rates and efficiencies (Ydenberg 1998). The rate of energy acquisition is typically modeled as the net energy acquired divided by the amount of time acquiring it. Energy efficiency is the amount of energy gained divided by the amount of energy expended. For example, within a minute, an animal could spend 1 calorie to acquire 10 calories (rate = 9 cal/min, efficiency = 10) or 10 calories to acquire 100 calories (rate = 90 cal/min, efficiency = 10). These

alternatives are equally efficient, but the latter provides an additional 81 calories per minute – a higher rate. The optimal choice might seem obvious in that example, so instead, imagine that the choice is between spending 1 calorie to acquire 10 calories (rate = 9 cal/min, efficiency = 10) or 50 calories to acquire 100 calories (rate = 50 cal/min, efficiency = 2). While the latter option still provides a much higher rate of return (an additional 41 calories per minute), it requires a very large investment of energy and is the less efficient option.

Several studies have directly tested which currency hypothesis is better supported by behavioral data. One of the first such studies revealed that starlings maximized the rate, not efficiency, at which they provisioned larvae to offspring (Kacelnik 1984). However, many studies since then indicate that animals make decisions that maximize efficiency instead of rate. In most of these cases, it appears that the efficiency currency may produce a better fit because it implicitly models hidden fitness costs experienced during foraging. Specifically, the amount of energy invested in foraging (the denominator of the efficiency equation) is frequently correlated to fitness costs such as exposure to predators, damage to feeding structures, or the build up of lactic acid in muscles (Houston and McNamara 2014). For example, feeding on larger mussels requires more energy, and that energy results in damage to the bills of oystercatchers. Therefore, while the rate of intake may be larger when feeding on large mussels, oystercatchers may instead maximize efficiency (and decrease damage) by selecting smaller mussels (Rutten et al. 2006). In general, it seems animal decisions maximize efficiency instead of rate when hidden costs limit their ability to expend energy.

fitness by avoiding predators, minimum energy requirements can be established as constraints and time spent foraging can be used as the currency. Moreover, diets consist of more than just calories; they also are the source of nutrients. The need for particular nutrients can result in diet choices substantially different than those predicted to optimize energy gains. In particular, narrow, high calorie diets may optimize the calorie currencies but not meet nutrient requirements, thus favoring broader diets not predicted by models maximizing calorie intake.

In socially complex species like humans, the social impact of behavioral decisions must also be taken into account. In a study on the hunting behavior of Ache men (Hawkes 1991), the subjects hunted more meat than predicted under the hypothesis that they were maximizing an energy currency. This indicated that an alternative or additional currency may also shape hunting behavior, such as potential mating advantages that arise from sharing meat.

Almost all optimality models start with the assumption that behavior should maximize genetic fitness. However, if the behavior of humans (or other animals) is influenced by cultural as well as genetic evolution, we might expect that models that maximize currencies related to both genetic and cultural fitness might better predict behavior. For example, imagine that the hunting meat and foraging for nuts provides approximately the same number of calories per unit of time or energy invested. However, the hunting of meat is somehow more memorable than foraging for nuts. While the genetic fitness associated with each diet is equal, the cultural fitness of hunting is higher, as each occurrence of hunting spreads the cultural traits more efficiently than each occurrence of nut foraging.

Beyond Energy and Darwinian Fitness

While the ability to gather energy is an important component of fitness, other components such as the ability to avoid predators might be better modeled by alternative currencies. For example, in a model hypothesizing that animals maximize

Constraint Assumptions

In economic models of behavior, “constraint assumptions” are hypothesized fixed properties of the environment (extrinsic constraints), the organism (intrinsic constraints), or their interaction. For example, in models of patch residence

(estimating how long animals should forage in a patch of resources before looking for another patch), the amount of time it takes to travel between patches is a constraint, as is the relationship between patch residency and resources received (the rate of resource accumulation is the currency in these models). The constraints can be thought of as the playing field on which the behavior occurs. Constraints are not necessarily invariable, but the behavior that the model is predicting does not change the constraint.

An approach pioneered by Belovsky (1978) illustrates how constraints establish the playing field on which foragers maximize a currency. In modeling the amount of aquatic and terrestrial plants included in an a moose diet, three constraints bound the potential diet composition: Each day, a minimum amount of aquatic plants must be consumed for sodium content, a maximum amount of plant mass can be consumed due to the limited size of the moose's gut, and a minimum amount of calories must be consumed. Data from moose indicate that their diet composition does indeed fall within the predicted space established by these constraints. Within that space, moose maximize caloric intake by only consuming as much of the bulkier aquatic plants needed to meet their sodium needs, and then choose the equally calorie-rich but less gut-filling terrestrial forage.

The predictive power of a model is dependent on how accurately it represents the actual constraints on the animal's behavior. When interpreting model fit, therefore, it is important to be aware of both the constraints that are explicitly described and those assumptions that are baked into the math or logic of the model. Giraldeau (2008) provides a useful list of both types of constraint assumptions. For example, models frequently explicitly assume that animals cannot handle prey and search for additional prey at the same time and that they encounter prey items one at a time. In contrast, constraints that often arise from the mathematical formulation of the model include the assumptions that all prey items within a particular category are equally valuable and that the encounter rate with prey items is constant.

Models with minimal intrinsic constraint assumptions are utilizing the "phenotypic

gambit;" the assumption that evolutionary or psychological constraints are so minimal that they are not required to effectively predict behavior. Cognitive ecologists have started to test models that explicitly model more limited cognitive constraints. For example, a typical assumption in prey selection models is that animals can immediately discriminate between the resources they are choosing among and that such discrimination is cost free. Psychological studies, however, reveal that animal "attention" is not unlimited, in particular when animals are engaged in difficult tasks, such as searching for inconspicuous prey. While animals searching for conspicuous prey are expected to include many prey species in their diet, animals searching for inconspicuous prey rely on search images and optimize their search by attending to one prey type at a time, even if other prey items are equally rewarding (Dukas 1998).

Conclusion

Evolutionary models of behavioral decisions aim to predict behavior based on particular hypotheses about the animal and its environment. Those hypotheses are the currencies maximized (or minimized) and the constraints acting on the organism. While empirical data occasionally tightly matches the predictions of optimality models, more often mismatch provides an opportunity to consider additional currencies or constraints that impact animal decisions. Most recently, cognitive ecologists have been able to use the rich comparative psychology literature to improve predictions by including hypotheses about constraints on cognition. Hopefully, the integration of cognitive constraints into these models might help bridge gaps between evolutionary psychologists and human behavioral ecologists.

Cyberbullying

Marilyn Campbell

Queensland University of Technology, Brisbane, Australia

Synonyms

[eBullying](#); [Electronic bullying](#); [Technological bullying](#)

Definition

Cyberbullying is a behavior conducted through technological means with an intention to hurt, is usually repeated and where there is an imbalance of power in the relationship.

Introduction

While bullying is a behavior which has occurred for most of human history, with the advent of technological communication, cyberbullying through this medium is now possible. There has been definitional controversy whether

cyberbullying is a form of bullying or another phenomenon. Further, there is disagreement about the severity of its consequences compared to face-to-face bullying. The roles involved in cyberbullying have been researched and the motives that lead individuals to conduct this behavior have been explored. However, prevention and intervention of cyberbullying is a consistent theme. To inform these efforts, the perspectives that cyberbullying is a maladaptive socially learnt behavior or an evolutionary adaptation need to be considered.

Definitional Controversy

Cyberbullying was first noticed late last century with the term used in a New York Times article in 1995. However, Bill Belsey, a Canadian, is widely credited with popularizing the term on his website. The controversy surrounds whether cyberbullying complies with the accepted definition of bullying or is a different phenomenon.

The traditional conception of bullying is based on Olweus' (1993) three pillars: the intention of the perpetrator to hurt or harm, that the behavior is usually repeated, and there is a power imbalance in the relationship by virtue that the victim cannot get the behavior to stop. Some researchers originally maintained that cyberbullying, despite its name, was a discrete form of aggression (Dooley et al. 2009). The arguments were that cyberbullied victims experienced more severe negative outcomes than face-to-face or traditional bullying (Campbell et al. 2012), although other studies have not shown this to be the case. The intention of cyberbullying to harm has not been questioned, however, there was debate about the repetitive nature of cyberbullying. This was based on the premise that a perpetrator might only bully once but the message can be redistributed or passed on causing a different kind of repetition (Dooley et al. 2009). It was also argued that the imbalance of power was not obvious in cyberbullying although some researchers have pointed to a technological advantage or the ability of the perpetrator to be anonymous. Other researchers have noted differences between traditional and cyberbullying in the

fact that in cyberbullying is 24/7 access, the permanence of the cyberbullying in cyberspace and the wide potential audience.

The argument against the view that cyberbullying is a different phenomenon is that physical bullying presents very differently from verbal bullying and social/exclusion bullying has its own manifestations. All forms of bullying are different from each other but all intend to hurt, are usually repeated and there is a power imbalance in that the victim cannot get the bullying to stop. In addition, victims of both traditional and cyberbullying have reported that being traditionally bullied is worse for them because of the embarrassment of being bullied in front of their peers (Corby et al. 2016). One of the most common arguments that cyberbullying is actually a form of bullying is the evidence that most victimized students were bullied both by traditional and cyber means (Cross et al. 2009) and that there are common predictors for perpetration of both forms of bullying (Kim et al. 2016). Most researchers now agree that cyberbullying is one of the four forms of bullying.

Prevalence

Although cyberbullying has been studied in the workplace, most research has been conducted with school students. There are unfortunately extremely different prevalence rates of cyberbullying reported among young people. Prevalence is usually measured by self-report, however, studies have been hampered by differences in participant recruitment, different data collection techniques, whether a definition is included (Ybarra et al. 2012) and if the behavior is measured by a global or behavioral question (Huang and Cornell 2015). Other issues include frequency cutoffs, the reference time selected, the age and country of the students (Selkie et al. 2016).

In a meta-analysis of 80 international studies, Modecki et al. (2014) found 15% of students were cyberbullied and 15% cyberbullied others. Katz and colleagues also in 2014 synthesized eight Australian studies reporting that approximately

20% of Australian students had been cybervictimized.

Consequences

Cyberbullying victims, similar to traditional victims have been shown to have increased anxiety, depression and social difficulties (Campbell et al. 2012), as well as decreased self-esteem (Chang et al. 2013) and substance abuse (Mitchell et al. 2007). It is not only those who are cybervictims who have negative outcomes but also cyberbullying perpetrators who also have depression, anxiety and social difficulties (Campbell et al. 2013) and high levels of stress symptoms (Cross et al. 2009). Those individuals who are both cyberbullied and cyberbully others have the most negative consequences with the worst scores on measures of physical and psychological health and academic performance (Kowalski and Limber 2007). Cyberbully victims are also more anxious, depressed and stressed, and less socially connected than those who are not involved in cyberbullying (Spears et al. 2016).

Motives for Perpetration of Cyberbullying

Many studies show that students who cyberbully profess the same motives as those who bully by traditional means. This is not surprising given the overlap between the two forms of bullying (Cross et al. 2009). The most widespread motive for cyberbullying is for the student to obtain dominance, power and social status. It has been suggested that bullying through technology can also lead to fast rewards such as the number of likes on Facebook. Cyberbullies can also strive for material gains and resources. Peer norms and peer pressure can also be motives for students to cyberbully.

Another motive that has been put forward for cyberbullying is that is fun and relieves boredom, it is something to do providing entertainment. Many adults believe that students who are found to be cyberbullying, excuse their behavior by

saying it was a joke, they were trying to be funny. However, it could be that with the absence of cues to elicit empathy and the peer norms of less polite behavior online, kidding around could be a genuine motive for some students to unintentionally hurt others. In addition, cyberbullying could be an act of revenge (Konig et al. 2010). With cyberspace providing a less physical environment than the schoolyard and with the ability to remain anonymous, it has been postulated that some traditional victims could cyberbully their playground bullies as they can obtain revenge without retaliation. Another motive has been suggested that it is easy to cyberbully and anyone who is different is fair game (Compton et al. 2014).

Theoretical Explanations of Cyberbullying Behavior

Two major theoretical perspectives of conceptualizing bullying are social learning theories and an evolutionary approach. These two explanations are not necessarily mutually exclusive and many of the solutions to bullying behavior seem very similar.

Social Learning Theory

To date most researchers explain cyberbullying behavior by social learning theories (Bandura 1986). Bandura's form of social learning theory, called social cognitive theory, comprises two main tenets that learning is by observation through modeling by the processing of information and by direct consequences. These basic concepts are an accepted part of most social learning theories.

The family is the main source of learning for children, especially in social relationships. When family dynamics are impaired and conflictual then children will tend to carry on conflictual relationships with peers including bullying perpetration (Low and Espelage 2013). Not only do children learn from the modeling of their parents about abuse of power, but harsh and conflictual parenting has been shown to influence young people's tendency to bully others (Bowes et al. 2009).

Sibling bullying within the family is also associated with more bullying of peers outside the family (Tanrikulu and Campbell 2015). In addition, low parental monitoring, especially on computers and mobile phones, allows children to engage in hurtful behaviors without negative consequences from their parents. Hinduja and Patchin (2013) found that young people who were punished for cyberbullying by parents were less likely to be involved in the behavior again.

Akers (1998) applied social learning theory to deviant behaviors of youth which he maintained were learnt by observation, imitation, differential associations (i.e., perceptions that the law can be violated), and differential reinforcement. Association with peers who are hurtful to others allows young people to conform to the group and engage in similar behavior. This behavior has also been found for youth who cyberbully (Holt et al. 2012). In addition, it has been shown that differential association was significantly correlated with cyberbullying behavior, that is, these young people thought there were no rules online and morally it was acceptable to write mean things (Li et al. 2015).

Evolutionary Explanations

Evolutionary psychology maintains that our behavior is shaped by genes that were evolved to be the most adaptive for humans in the past (Kolbert and Crothers 2003). One widespread behavior that has provided a competitive advantage in interspecies behavior is aggression. However, within-species violence is potentially nonadaptive. Thus, within cooperative species such as primates and humans it is argued that dominance hierarchies have evolved to restrain the negative effects of aggression and thus provide social stability.

This theory has been applied to childhood bullying which is postulated to be one of the central ways to establish dominance hierarchies in school systems (Kolbert and Crothers 2003). If there are stable hierarchies and young people know “their place” in the peer groups this is said to prevent destructive fighting in the group. Bullying is conceptualized as providing the perpetrator with social power to maintain the status quo.

Some recent research, however, has challenged this theory of bullying providing social stability in groups in young people. It has been found that there is actually much instability of bullying perpetrator roles (Le et al. 2017) where those students who self-reported bullying behavior at time 1 did not continue with this behavior at time 2 six months later. While it has been recognized that this changing of roles happens in very young children (Monks et al. 2003), these are the first studies to show changes of roles in bullying also occurs with secondary school students.

In considering cyberbullying from an evolutionary perspective it is necessary to decide if cyberbullying is an evolutionary adaptive tool. As previously argued, cyberbullying is one form of bullying, different in some of its manifestations from physical, verbal, and social bullying which are different from each other, yet all are forms of bullying. Therefore, the question becomes is bullying an evolutionary adaptive behavior? There are three major discussion points in this argument: is bullying heritable, is it goal related, and is it ecologically based (Volk et al. 2016).

The first point is heritability, is there an inherited component to this behavior? The genetic evidence is scant, with only Ball et al. (2008) providing some evidence with a twin study finding a heritability coefficient of 0.61. However, bullying is also very widespread and found in every country where it has been studied (Book et al. 2012) and throughout history (Rawson 2003). The behavior is also extremely hard to reduce (Ttofi and Farrington 2011).

The second point, is bullying goal-related? It has been shown that many students bully for social dominance (Reijntjes et al. 2013) or for physical resources such as food or money (Volk et al. 2015). Social dominance is particularly important in times of transition from elementary to middle school when peer networks are disrupted and need to be reestablished (Cross et al. 2009).

The third point is that adaptive aggression is conducted within a local ecology which influences how aggression is expressed (Hawley 2015). The argument is that societal toleration of bullying shows it is a sanctioned ritual for

establishing a dominance hierarchy (Kolbert and Crothers 2003). While this may have been the case previously since the work of Olweus and Smith in the last 40 years in demonstrating the negative outcomes from bullying societal attitudes in most countries have changed. As Hawley (2015) argues, however, because hierarchies are pervasive in nature does not make them morally correct or even healthy.

Prevention and Intervention Efforts

Examining cyberbullying through the two lenses of evolutionary psychology and social learning theory, it would seem cyberbullying behavior could, in part, be evolutionarily adaptive and maintained by social learning. Both theories offer explanations of why people behave as they do. How therefore, do the two explanations inform prevention and intervention efforts? Even if cyberbullying is adaptive evolutionary that does not mean it is acceptable (Hawley 2015).

It is known that bullying is widespread, historical and is very hard to reduce. This could be as the behavior is goal-directed with more benefits than cost then it is not easy to change. Ecologically if bullies are seen as lacking in social skills then by providing these skills this should reduce bullying, but this is not the case (Ttofi and Farrington 2011). This could be because most students who bully are socially popular (Reijntjes et al. 2013). There are probably two types of students who bully. Those who are socially skilled and popular (but often not liked), who adults would not see as being involved in bullying. Therefore, these students obtain the rewards with no costs associated, learn to abuse their power, and carry that into their working life to become workplace bullies. Then, there are those students who fit the stereotype of the maladaptive bully.

Evolutionary psychologists studying bullying have suggested two ways in which to reduce bullying in students. First, Volk et al. (2016) contend that bullies cannot be asked to relinquish their power and therefore one way to be able to accomplish this is by increasing the cost of bullying to

them. This would seem to indicate more negative consequences should be applied to these students showing this behavior, either from adults, such as parents or teachers, or from their peer group by ostracizing them. Motivational interviewing could also be a strategy to convince these students to change their behavior but only if there was costs to their behavior as well as rewards. The second suggestion by Volk and colleagues (2016) is to offer students who bully other ways of obtaining what they want, that is power and affiliation. Hawley (2015) advises substituting prosocial behavior for antisocial behavior for these students to maintain their power in the dominance hierarchy. Along the same lines, Kolbert and Crothers (2003) suggest using the concept of eminence instead of domination, that is, using the student's ability to influence their peers in positive and not negative ways.

At present, schools try to educate all students in the same way about bullying, which could work for prevention especially for the bystanders. However, it would seem more logical that as students who bully do so for various reasons within different ecological frameworks that intervention needs to be tailored to the individual as one needs to know their particular motives to address their needs to encourage them to change their behavior.

Conclusion

Cyberbullying is a worldwide public health problem, especially among young people. It is generally agreed that it is a new form of bullying with negative consequences for all involved. Most researchers conceptualize bullying in terms of social learning theories, where young people learn behaviors through modeling and operant conditioning. However, more recently evolutionary psychology has proposed an alternative framework that bullying behavior may be a biological predisposition. Whichever theory is proven to be more likely, the intervention strategies appear to be broadly agreed upon. Future research is needed to explore both these viewpoints.

Cycle Variation

Lauren Smith and Aron Wiegand
State University of New York at New Paltz,
New Paltz, NY, USA

Synonyms

Change in ovulatory cycle; Menstruation; Ovulation; Ovulatory cycle phases

Definition

Cycle variation is the different stages of the female ovulatory cycle, which occurs in fertile women.

Introduction

Human females have evolved ovulatory cycles that are different than the reproductive cycles of

other mammals. The ovulatory cycle in human females lasts 28 days on average. During different stages of the ovulatory cycle, physiological and behavioral changes can be observed. In the ovulatory stage, when a woman is capable of reproduction, females have exhibited a change in mating behavior and mate preference. Men also perceive women differently depending on which stage of the cycle females are in.

The Evolved Ovulatory Cycle

The reproductive cycle varies across species, with humans being especially unique. Most female mammals have estrous cycles, commonly referred to as being in heat. During the estrus phase of the cycle, females who are not taking care of infants display mating behaviors and signals to alert males of their ability to reproduce. These cycles are often related to external conditions, such as the time of year and prevalence of resources. Human females, on the other hand, evolved more regular cycles known as ovulatory cycles in which both ovulation and menstruation occur on a monthly basis, regardless of the time of year (McElroy and Townsend 2015).

Human females become fertile after the onset of menarche, or the first menstrual period, which generally occurs in adolescence, usually between the ages of 11 and 18. When females are no longer able to menstruate, they are no longer capable of reproduction, which is referred to as menopause. Menarche and menopause are often influenced by a variety of factors, including nutrition, overall health, and one's environmental conditions, or life history strategy. Unlike many other female primates, human females are able to live many years after the cessation of ovulation, which some researchers explain as the "grandmother hypothesis," originally contrived by Williams (1957). This idea posits that it is adaptive for older females who are not reproducing to help their own kin with child-rearing. There is also the "prudent mother hypothesis" which suggests that women lose the ability to reproduce in midlife because the developing fetus is at greater risk and it is more adaptive for women of this age to be

taking care of their kin (McElroy and Townsend 2015).

The human ovulatory cycle consists of two phases and is related to the various hormones present at each stage. The cycle begins with the follicular phase, which lasts from the first day of menstruation to ovulation. In this phase, estradiol levels rise until they reach their peak at ovulation, and an egg is released into the fallopian tube. If the egg is fertilized by male sperm, the female may become pregnant. In the luteal phase, the body prepares for pregnancy and releases progesterone and estradiol. If the egg is not fertilized, menstruation (i.e., blood withdrawal) occurs and the cycle repeats itself (Reed and Carr 2015).

The ovulatory cycle has been studied to have an effect on a female's behavior and additionally how she is perceived by males, as discussed more in depth in the section on concealed ovulation. A number of researchers have studied the effect of ovulation on behavior and female attractiveness. Schwarz and Hassebrauck (2008) found that women are perceived as more attractive at the peak of fertility in the ovulatory cycle by themselves and by men. Additionally, Puts et al. (2013) showed that females were rated as more attractive at the peak of fertility.

Conclusion

Ovulatory cycles are unique in humans in such a way that ovulation occurs in a cyclical pattern that consists of two phases, the follicular phase and the luteal phase, with ovulation occurring at the midpoint of an approximately 28-day cycle. During ovulation, females are perceived as more attractive and experience a change in behaviors that can be related to underlying sexual drives.

[Darwinian ethics](#); [Ethical issues](#); [Evolutionary theory](#)

Definition

Evolutionary theory has been used to support a range of political ideologies and social policies, including unethical behaviors.

Introduction

Evolutionary theory, and natural selection in particular, has been utilized to justify a range of political ideologies and social policies, from conservatism to liberalism and individualism to socialism (Hodgson 2004). Consequently, while evolutionary theory may enhance scientific understanding and has been used to promote positive behavior, it has also been misappropriated to support a range of unethical acts. These include incarceration, discrimination, and genocide. The current entry outlines the misuse of evolutionary theory to justify Nazi ideology, with particular emphasis on the classification and separation of racial groups and the promotion or constraint of reproduction among those deemed to be superior or inferior, respectively. Throughout, the manner in which this ideology and subsequent social policy is inconsistent with evolutionary theory is emphasized. Indeed, the conclusions reached by those interpreting scientific (or pseudoscientific) theories are often more indicative of prior motivation and bias than the theories themselves.

Hitler and the Misuse of Evolutionary Ethics

Darwin focused on the manner in which evolution occurred rather than manner in which this should inform policy. He did, however, apply evolutionary theory to humans and acknowledge the manner in which prior struggle had contributed to the development of the species. In the *Descent of Man*, Darwin (1882) stated

Man, like every other animal, has no doubt advanced to his present high condition through a struggle for existence consequent on his rapid multiplication; and if he is to advance still higher he must remain subject to a severe struggle. Otherwise he would soon sink into indolence, and the more highly-gifted men would not be more successful in the battle of life than the less gifted. Hence our natural rate of increase, though leading to many and obvious evils, must not be greatly diminished by any means. There should be open competition for all men; and the most able should not be prevented by laws or customs from succeeding best and rearing the largest number of offspring.

Hitler, in contrast, focused on the manner in which evolutionary principles (and in particular the aforementioned struggle) should influence society (Weikart 2009). He believed that stronger and weaker members of a species exist, there is a struggle in which these individuals compete, and stronger members of the species survive leading to biological advancement of the species. Therefore, future development was assumed to be dependent on further struggle and the success of superior individuals. Factors leading to the improved health of the species were viewed as ethically good, whereas those leading to the stagnation or decline of the species were believed to be immoral. Specifically, “There is only one holiest human right, and this right is at the same time the holiest obligation, to wit: to see to it that the blood is preserved pure and, by preserving the best humanity, to create the possibility of a nobler evolution of these beings.” Social policies introduced included discrimination, eugenics, and population expansion, which it was argued would promote evolutionary progression and avoid biological deterioration. As stated by Hitler “It is absolutely true that first of all the law of

selection exists in the world, and nature has granted the stronger and healthier the right to life. And rightly so. Nature knows no weakling or coward, it knows no beggar, etc., but rather nature knows only those who stand firm on their soil, who sacrifice their life, and indeed sacrifice it dearly, and not those who give it away.”

Evolutionary theory and the description of intraspecies competition do not of course justify Nazi social policy. Though evolutionary principles have been employed to explain a range of negative behaviors such as rape (Thornhill and Thornhill 1983), homicide (Liddle et al. 2012, and abuse (Daly and Wilson 1985), we should not equate understanding those behaviors with endorsement of them. Furthermore, the “solution” does not necessarily follow from the identification of a social “problem.” For example, while apparent differences in IQ between racial groups have been used to justify prejudice and discrimination, they could be used to question the validity of the testing process or to promote equality of opportunity and education. Furthermore, though Darwin described the manner in which competition influenced the evolutionary process, he also advocated support for poorer sections of society. He stated “The aid which we feel impelled to give to the helpless is mainly an incidental result of the instinct of sympathy, which was originally acquired as part of the social instincts, but subsequently rendered in the manner previously indicated, more tender and more widely diffused. Nor could we check our sympathy, even at the urging of hard reason, without deterioration in the noblest part of our nature” (Darwin 1882).

Highlighting an alternate approach, Dickens et al. (2012) address the subject of teenage pregnancy in the United Kingdom (and in particular pregnancy among those from low socioeconomic groups) from an evolutionary perspective. The researchers do not recommend measures intended to reduce reproduction among women from these socioeconomic groups (who are more likely to experience poor health and lower educational success), as may perhaps be proposed by those adopting the traditional eugenics-based approach to evolutionary theory. Based on life history theory, it is instead suggested that those wishing to

lower teenage pregnancy rates among low socioeconomic groups focus on improving the environment in which these reproductive decisions occur. In poor quality environments, with few resources, individuals are most likely to produce a greater number of offspring with relatively low levels of investment in each. Those living in these environments are most likely to begin reproduction at an early age. Predictable well-resourced environments are associated with high levels of investment in a small number of offspring. The influence of environment type is referred to as r (growth rate of the population) and K (capacity of the environment) selection. From this perspective, teenage mothers from low socioeconomic backgrounds are following a fast life history appropriate to the ecological niche in which they exist. Hence, social policies intending to reduce teenage pregnancy should focus on improving the quality and stability of the environment, e.g., reducing deprivation and crime.

Racial Differences

While Darwin focused on the variation which occurs between individuals, Hitler argued that races of people were superior or inferior. This racial policy was fundamental to Nazi ideology. He argued that “nationality or rather race does not happen to lie in language but in the blood.” He reasoned that as these differences were biological in nature, education or similar interventions were not sufficient to address racial differences. For example, in *Mein Kampf* Hitler stated that it is “criminal lunacy to keep on drilling a born half-apie until people think they have made a lawyer out of him, while millions of members of the highest culture-race must remain in entirely unworthy positions.” The benefit of education was for Hitler in the reaffirmation of an inherent positive character rather than the reverse of biologically inherited traits. Hence, he promoted racial classification, separation of the races, and treatment according to racial category.

As part of his emphasis on group characteristics, the Aryan race was described as physically, intellectually, and morally superior to other races.

In contrast, Jewish people were particularly targeted by Hitler and often portrayed as sexually perverted, immoral, and selfish. For example, he stated “In his vileness he becomes so gigantic that no one need be surprised if among our people the personification of the devil as the symbol of all evil assumes the living shape of the Jew.” Hitler frequently dismissed individual human rights and freedoms in favor of the importance of group cohesion and sacrifice. For example, he stated “For evolution requires willingness on the part of the individual to sacrifice himself for the community.”

The identification of one individual (or group) of superior quality is of course problematic. The notion that fitness can be assessed on status or achievement implies that individuals compete from an equal position. There are however a range of social inequalities (such as access to an elite education, medical care) which influence the achievement of specific social groups. Similarly, racist ideology suggesting that Caucasian Europeans and those of European descent are stronger than other races (based on greater accumulation of economic wealth) neglects the importance of environment and the specific ecological niches occupied (see Diamond 1997 for a review). Further, there are multiple interpretations of fitness or quality, and we may be unaware of the benefits and costs associated with specific physical or psychological traits. For example, though sickle cell anemia is a serious disorder associated with stroke and pulmonary hypertension (thus likely to be interpreted as weakness under the Nazi regime), those carrying the gene display resistance to malaria.

Promoting Reproduction in Superior Races and Reducing Reproduction in Inferior Races

Hitler frequently referred to the struggle for existence and the importance of that struggle, which he regarded as central to the progression observed in all species. Hitler repeatedly warned that failure to adhere to these “laws of nature” would lead to stagnation or degradation of the human race. For example, he stated “We are all beings of nature, which – inasmuch as we can see it – only knows one harsh law, that gives the right of life to the

stronger and takes the life of the weaker. We humans cannot except ourselves from this law..." He introduced a range of measures based on this ideology intended to facilitate reproduction among those deemed to be stronger or superior and remove weaker or inferior members of a species in order to enhance the natural evolutionary process. Of course, the existence of evolution does not imply that we should seek to enhance the process via artificial selection.

Hitler frequently promoted reproduction among those deemed to be of superior race. For example, he introduced loans to facilitate marriage at an early age and further financial incentives for those producing large numbers of children. Indeed women could be awarded bronze (four children), silver (six children), or gold (eight children) medals for producing many children. He believed that increasing the German birth rate (and therefore the population) would promote the competition necessary for evolutionary progression. He also expected this to ensure the presence of a strong military presence in future generations. Similarly, Hitler opposed those practices believed to threaten the increased reproduction of the Aryan race such as contraception and abortion, though of course these were desirable for other "inferior" races. Essentially those behaviors which led to the production of healthy children of the superior race were believed to be ethically right, whereas those leading to no offspring or inferior offspring (as believed to be the result of mixed race relationships) were labeled immoral.

He stated "For as soon as procreation as such is limited and the number of births diminished, the natural struggle for existence which leaves only the strongest and healthiest alive is obviously replaced by the obvious desire to 'save' even the weakest and most sickly at any price, and this plants the seed of a future generation which must inevitably grow more and more deplorable the longer this mockery of Nature and her will continues." He was particularly critical of homosexuality, stating "The homosexual is always disposed to drive the selection of men toward the criminal or at least sickly rather than the useful in the selection of men. If one would give him free

rein, the state would in time be an organization of homosexuality, but not an organization of manly selection. A real man would defend himself against this endeavour, because he sees in it an assassination of his own evolutionary possibilities." There is however a wealth of evolutionary literature identifying the potential evolutionary benefits of homosexuality and existence of homosexuality in nonhuman species (e.g., MacFarlane et al. 2010).

In this context, the invasion of other countries can be conceptualized as an attempt to secure additional land and resources to support the expanding Aryan race. Hitler reasoned that these resources were there to support the stronger race and facilitate progression of the species. He stated

War belongs to those events that are essentially unalterable, that remain the same throughout all times and only change in their form and means. Nature teaches us with every insight into its functioning and its occurrences that the principle of selection rules over it, that the stronger remains victor and the weaker succumbs. It teaches us that what often appears to an individual as brutality, because he himself is affected or because through his education he has turned away from the laws of nature, is nonetheless fundamentally necessary, in order to bring about a higher evolution of living organisms.

In addition to introducing measures intended to increase birth rates among the Aryan race, Hitler also attempted to limit or eliminate reproduction among those deemed to be inferior. Those in poor health (chronic health conditions or disabled) and those from non-Aryan races were primarily targeted. Indeed, eliminating hereditary illness and preventing mixture of the races were primary objectives for Hitler and the Nazi regime. He believed that children of unhealthy parents or resulting from mixed race relationships would be of intermediate quality and were capable of slowing or reversing evolutionary progression. Hitler described the outcome of mixed race relationships

Such mating is contrary to the will of Nature for a higher breeding of all life. The precondition for this does not lie in associating superior and inferior, but in the total victory of the former. The stronger must dominate and not blend with the weaker, thus sacrificing his own greatness. Only the born

weakling can view this as cruel, but he after all is only a weak and limited man; for if this law did not prevail, any conceivable higher evolution of organic living beings would be unthinkable.

Hence, a number of policies were introduced such as relaxing criteria for abortions, prevention of “inappropriate” relationships, and sterilization. Hitler believed that this form of artificial selection was consistent with the action of natural selection and would improve the biological quality of the human race.

As previously stated, attempts to assess quality (characteristic of the Nazi regime) fail to capture the benefits associated with conditions such as personality disorders or may inappropriately emphasize qualities such as physical strength to the neglect of others, e.g., creativity. For example, while those with personality disorders have a lower life expectancy (Fok et al. 2012) suggesting that the disorders are maladaptive, some disorders are associated with increased mating success (Sansone et al. 2011). Hence, those with (at least some) personality disorders may achieve greater reproductive success, and the trait could be considered adaptive. Indeed, the notion that social policy should seek to reduce variation and improve the quality of the species by promoting a limited number of qualities is flawed. Variation within a species increases resilience and allows individuals to take advantage of different ecological niches. This is clearly demonstrated by the relative success of dark and light varieties of peppered moths (*Biston betularia*). Furthermore, sterilization programs may be criticized both from ethical and scientific perspectives. For example, defective genes are often recessive, with defects frequently occurring through mutation; hence, sterilizing those affected by visible abnormality would have little impact.

Conclusion

Hitler reasoned that behavior should be regarded as ethical or unethical according to the impact that the behavior had on the progression of the species. For example, while abortion was believed to be unethical for members of the Aryan race, it was

acceptable (and encouraged or required) for those believed to be of an inferior race. Though Hitler often used evolutionary theory to justify his actions, his conclusions represent a misunderstanding of evolutionary theory and the use of pseudoscientific research. The dangers arising from this approach are clear. It is important to advance our scientific knowledge, separate explanation of behavior from formation of social policy, and challenge those misappropriating scientific theory to justify their own political ideology.

Daniel Dennett on Free Will

Dillon Bowen
University of Cambridge, Cambridge, UK

Synonyms

[Freedom](#); [Self determination](#)

Definition

The ability of rational agents to act out of self-determination; to select actions from a broad set of possible alternatives based on rational expectations of their consequences.

Introduction

Daniel Clement Dennett, an American philosopher and cognitive scientist from Tufts University, is one of the most influential living thinkers on the topic of free will. According to Dennett, free will is an “ability to see probable futures – futures that seem like they’re going to happen – in time to take steps so that something else happens instead” (Closer to Truth 2014).

Dennett’s view on free will falls under the umbrella of compatibilism, which holds that free will is compatible with determinism. Whether the universe is deterministic or indeterministic, Dennett claims, has no practical implications for concepts of moral responsibility and is therefore irrelevant to the question of whether or not an agent has free will. He has argued extensively against libertarian thinkers, such as Robert Kane, who maintain that certain kinds of agents have free will in light of the fact that their actions are indeterminate, as well as against eliminativists.

Dennett has also criticized eliminativists, like Sam Harris, who deny that agents do or could have free will. While Dennett denies the existence of absolute free will, he maintains that the non-absolutist sense in which most humans have free will is sufficient for moral responsibility and serves as the conceptual bedrock of praise and blame as well as reward and punishment.

Compatibilism

The version of free will Dennett defends can exist in a deterministic world; one in which “all physical events are caused or determined by the sum total of all previous events” (Dennett 1984 p. 1). Opposing this view is incompatibilism, which states that free will and determinism are incompatible. According to incompatibilism, if all our actions are the product of physical causes – that is, all actions and the consequences thereof are determined – then no one can ever be said to have acted freely. The claim the free will can exist even if all actions are determined is *prima facie* paradoxical.

Dennett dispels this paradox by distinguishing the concept of *determination* from that of *inevitability* (Dennett 1984). Even if future states of the world were determined, they would not be inevitable – that is, they would not be unavoidable. Intentional agents (Dennett 1988) are capable of making accurate predictions about future states of the world conditional upon the performance of certain actions, and then selecting among possible actions to avoid the less desirable of these possible future states. For example, if someone were to see a brick being thrown at them, they could accurately predict that the brick would hit them conditional upon not moving (and that the brick would not hit them conditional upon ducking out of the way) and elect to duck in order to avoid being hit by the brick. In this sense, future states of the world may be “evitable” even if they are determined.

In the same way that determinism does not imply inevitability, Dennett claims that determinism does not imply that one “couldn’t have done otherwise” (Dennett 2003). The relevant

question to assess if an agent could have acted otherwise in a given situation is not whether the action was determined *per se*, but whether the action was determined *by factors external to the agent*. According to Dennett, the self can be roughly identified as the brain, or at least the part of the brain responsible for conscious action (Dennett 1992; Hofstadter and Dennett 1982). Actions are therefore the product both of one's self – that is, one's beliefs, desires, and capacity for rational action – and external factors. Considering an agent's decision retroactively, would changing some of the factors internal to the agent, along with slight variations in the external conditions, have led to her choosing a different course of action? If so, then she could have done otherwise.

Even in a deterministic universe, future states of the world would not necessarily be inevitable, nor would agents be incapable of having acted otherwise. Both evitability and the capacity to have done otherwise are requirements for having free will. In addition to the claim that indeterminism is unnecessary for free will, Dennett defends the stronger claim that indeterminism adds nothing valuable to our concepts of free will and moral responsibility (Dennett 1978). In his 1978 book *Brainstorms*, Dennett develops a two-stage “Valerian” model of an agent with free will in an indeterministic world. During the first stage, the agent's consideration-generator utilizes a randomized algorithm to generate a set of possible outcomes with probabilities conditional upon certain actions. During the second stage, the agent's reasoning processes select which actions to perform based on the output of the consideration-generator. The virtue of the Valerian model is that it incorporates indeterminacy into the decision-making process while allowing the agent to maintain control over its actions. However, such an agent would be no different in any morally or practically important sense from a deterministic agent whose consideration-generator operated according to a pseudorandom algorithm. Dennett claims more generally that pseudorandomness can be used as a morally and practically equivalent substitute for actual randomness in any libertarian model of free will.

A Free Will Worth Wanting

The criteria Dennett employ to construct his view of free will are based on the ethical and social function he envisions a concept free will fulfilling. In his own words, “Don't try to use metaphysics to ground ethics. . . ; put it the other way around: use ethics to ground what we should mean by our ‘metaphysical’ criterion” (Dennett 2003, p. 297). Specifically, the function of free will should be to ground notions of moral responsibility, praise and blame, and reward and punishment. Dennett is a consequentialist viewing punishment as a tool for discouraging bad behavior and reward as a tool for encouraging good behavior. The type of free will which can fulfill this function is a “free will worth wanting” (Dennett 2003).

According to Dennett, the primary utilitarian function of punishment is deterrence. However, only a certain class of agents are capable of responding to incentives such that deterrence would be effective for them. Dennett refers to this class of agents as the “Moral Agents Club” (Santa Fe Institute 2014). The threat of punishment provides reasons for not taking certain actions, and only agents capable of responding to these reasons can be held morally *responsible* for their behavior. In order for punishment to fulfill its role as a deterrent, it will be sufficient to punish only morally responsible agents. Extending punishment to morally irresponsible agents would be gratuitous insofar as it causes unnecessary harm for no utilitarian end. Accordingly, the concept of free will should be crafted to distinguish between morally responsible and irresponsible agents for the purposes of selectively assigning punishment in a socially optimal manner (Dennett 2003).

Dennett identifies six criteria which together are necessary and sufficient conditions for an agent to act freely (Santa Fe Institute 2014). The agent must:

1. Be well-informed
2. Have well-ordered desires
3. Be moved by reasons
4. Not be under the control of another agent
5. Be punishable
6. Be able to have acted otherwise

One desirable feature of a sense of moral responsibility based on these criteria is that it allows members of the Moral Agents Club to enter into enforceable contracts (Dennett 2003). For example, when signing a mortgage agreement, the mortgage lender can reasonably expect the borrower to repay her debt. If she refuses, she will face some sort of punishment and, as a morally responsible agent, the lender knows that the threat of punishment will motivate her to keep the contract. Another desirable feature of these criteria is that they do not require agents to be absolutely free in order to be responsible (Dennett 2003). Rather, free will and moral responsibility exist on a continuum, whereby an agent is free and responsible to the extent that she embodies these criteria. This allows Dennett to acknowledge that actions are partly determined by external factors while maintaining that most humans are free and responsible enough to participate in social contracts.

Finally, it is important to distinguish between a free will *worth* wanting and the free will most people *think* they want. Several studies in experimental philosophy suggest that people believe free will is incompatible with determinism, desire an absolutist contra-causal version of free will, and wish to use this absolutist free will to justify retributive punishment (Harris 2012). Dennett acknowledges that this sort of free will is indeed what people want and that it does not exist. However, he maintains that his version of free will both exists and is *worth* wanting, in the sense that the social benefits it produces are at least as substantial as those which could be guaranteed by absolute free will.

Freedom Evolves

As a naturalist and secularist, Dennett does not believe that free will is something granted by God (from the top down) but rather something that evolves through biological and cultural evolution (from the bottom up) (Dennett 2003). The history of evolution is the history of increasing “evitability,” as organisms develop better

mechanisms by which to optimally respond to their environment. Accordingly, Dennett maintains that the correct level at which to think about free will is not the physical level but the biological level (Closer to Truth 2014). Biological evolution has seen an arms race of evitability: for instance, predators evolve traits which allow them to avoid missing their prey, and prey evolve traits which allow them to avoid being eaten by predators. The evitability arms race may have been particularly important in the evolution of human social interactions, for example, as people evolved traits to avoid being cheated and cheaters evolved traits to avoid being detected (Byrne and Whiten 1988).

Dennett’s view of the relationship between biology and free will stands in contrast to that of B. F. Skinner, the father of behaviorism, who viewed psychology as having dispelled the idea of an inner free agent (Skinner 1971). In response, Dennett catalogued how, over the course of biological history, evolution has selected for creatures with increasingly greater levels of competence and freedom (Dennett 1996). One of the earliest and most basic creatures is the eponymous Skinnerian creature, which engages in trial-and-error learning absent of forethought, and does not have free will in any meaningful sense. Then came the more advanced Popperian creature, which exhibits forethought by selecting actions on the basis of their expected consequences (this creature is named after Karl Popper, who promoted the idea of falsificationism, as the Popperian creature allows its hypotheses to die in its stead). Later and more advanced still is the Gregorian creature, named after information theorist Richard Gregor, which augments its forethought by using thinking tools, such as language. Finally, the modern-day pinnacle of competence and freedom is the Scientific creature, which utilizes systematized social learning processes to improve its model of the world. Dennett contends that the level of competence and free will human beings enjoy as Scientific creatures results from biological and cultural selection pressures for advanced individual and social learning (Dennett 2003).

Criticism and Responses

Dennett's views on free will have been criticized in recent years by a number of scientists and philosophers, perhaps most notably Sam Harris (e.g., Harris 2012, 2014; Kane 1996; Pereboom 2001; Strawson 1994, 2003; Van Inwagen 1983). The main criticism is a terminological critique, which argues that Dennett's definition of "free will" disagrees so drastically with the commonplace notion of free will that his use of the term in public discourse is confusing and disingenuous. Harris has analogized the way Dennett justifies belief in "free will" to the way some theologians justify their belief in "God": by attaching idiosyncratic meanings to established terminology (Harris 2012). According to Galen Strawson, "[Dennett] doesn't establish the kind of absolute free will and moral responsibility that most people want to believe in and do believe in. That can't be done, and he knows it" (Strawson 2003).

Initially, Dennett replied by arguing that his definition of free will did have an established meaning within certain subdisciplines of philosophy (Dennett and Harris 2014). Criticizing him for using an established technical term, even if misunderstood by the general public, would be like criticizing scientists studying "color vision" for using the term in a way that disagreed with the commonplace concept of color vision. Furthermore, Dennett said, he was less interested in establishing the sort of free will that people want to and do believe in than establishing the sort of free will that is objectively worth wanting (see section "Introduction"). However, as a result of critiques by Harris, Strawson, and others, Dennett now believes the term "free will" engenders such confusion in intellectual and public discourse that it may be more useful to talk about moral responsibility in the absence of free will (Harris 2016; Santa Fe Institute 2014).

Conclusion

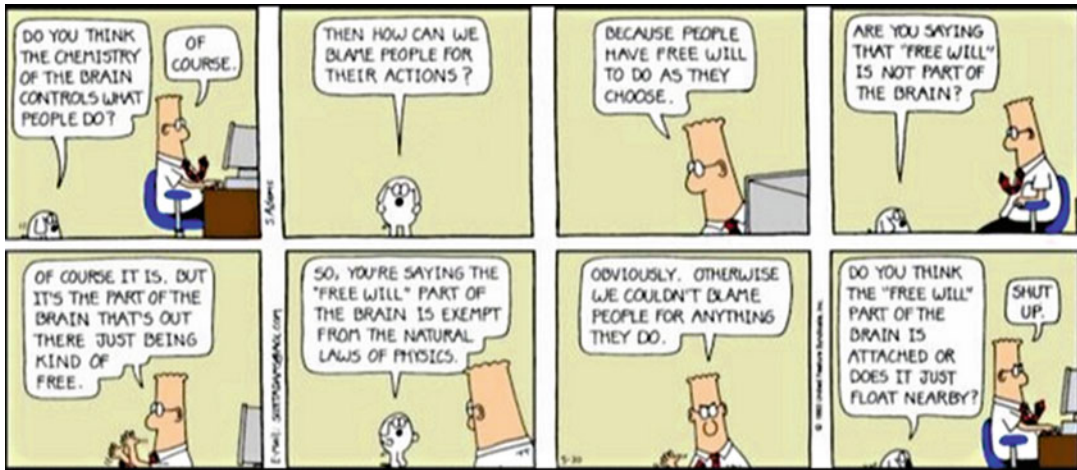

According to Daniel Dennett, free will is an "ability to see probable futures – futures that seem like

they're going to happen – in time to take steps so that something else happens instead" (Closer to Truth 2014). Dennett is a compatibilist, meaning that he believes free will and determinism are compatible. In a deterministic world – one in which all future events are determined by prior events – an agent's fate would not necessarily be inevitable nor would it be the case that she "couldn't have done otherwise" in a given situation. Moreover, Dennett claims that indeterminism does not add anything valuable to the notion of moral responsibility, making it practically irrelevant to the concept of free will.

Dennett believes that the metaphysical criteria used to determine whether or not an agent has free will should be based on the ethical and social function free will is supposed to perform; to ground notions of moral responsibility, praise and blame, and reward and punishment. Such a free will is a "free will worth wanting." From a utilitarian perspective, Dennett believes that punishment should serve as a deterrent by providing reasons against taking certain actions. Only agents capable of responding to these reasons can be held morally *responsible* for their behavior. Therefore, the concept of free will should be crafted to distinguish between morally responsible and irresponsible agents for the purpose of selectively assigning blame and punishment. (Similar logic applies when assigning praise and reward).

The history of evolution, in Dennett's view, has been an arms race of "evitability," as selection pressures have favored complex biological machines which are increasingly capable of anticipating and responding to possible future states of the world. Part of this history is the evolution of advanced cognitive capacities, such as augmented thinking tools and social learning mechanisms, the development of which can be viewed as the gradual evolution of freedom. These advanced cognitive capacities are especially pronounced in humans, who represent the modern apex of free will.

Dennett's views on free will have been criticized by a number of scientists, philosophers, and authors, whose primary concern is that using the term "free will" in public discourse ostensibly

Daniel Dennett on Free Will, Fig. 1 Daniel Dennett's favorite cartoon on free will

implies a belief in absolute freedom and retributive punishment. Though Dennett takes care to explicitly denounce this implication, he now believes that it may be more rhetorically pragmatic to focus on moral responsibility than on free will (Fig. 1).

Daniel Dennett: A Review of His Evolutionary Work

Robert King
School of Applied Psychology, University
College Cork, Cork, Ireland

Synonyms

Consciousness; Dual inheritance; Evolution;
Humor; Intentional stance; Memes

Introduction

Daniel Dennett is the codirector of the Center for Cognitive Studies, and the Austin B. Fletcher Professor of Philosophy at Tufts University. He is a philosopher in the analytic tradition but, unlike many of his contemporaries, has taken the trouble to familiarize himself with the nuts and bolts of empirical work. This has meant that over a six-decade career, he has made consistent and useful contributions to evolutionary scholarship, clarifying issues, generating research programs, and inspiring the next generation of scholars.

The Scope of Dennett's Philosophy of Science

"The aim of philosophy, abstractly formulated, is to understand how things in the broadest possible sense of the term hang together in the broadest possible sense of the term" (Sellars 1963, p. 35). This goal of pragmatist philosophy has been an explicit aim throughout Dennett's career. Sellars divided the world into the *scientific* image – for example, the world of particles and forces, and the *manifest* one – that this is the ontology accessed by commonsense, aided by logical reflection on the twin philosophical horns of necessary and contingent truths. The manifest image contains such things as colors, intentions, beliefs, and

(latterly) memes. A sensible way of summarizing one of the major themes of Dennett's work would be to say that he has achieved more than most in showing how these disparate elements can, or cannot, be made to live together coherently.

From the very inception of psychology as a science, a fundamental divide opened up in terms of seeing how much behavior could be explained by top-down mechanisms (such as social norms) versus that which could be explained by bottom-up mechanisms (such as stimulus–response schedules). Dennett is unusual in that he has argued consistently that both bottom-up and top-down approaches (which we would typically now call genes and culture, respectively) are subject to Darwinian selection. He thus embraces a dual-inheritance model.

Social constructionists (and others) are apt to make much of the fact that worlds of shared intentionality account for much of the so-called objectivity that we find in the world. Many thereby seek to undercut this sense of objectivity, by pointing out that humans could, if they wished, change this shared social space. Often the focus here is on language – and language change. However, objective reality is, in key ways, even more fragile than social constructionists can accept in their wildest dreams. Take a property like color. Naïve realism says that color is a real property of objects. However, naïve realism does not last long against optical illusions and neuroscience. However, a social constructionist might go further – by trying to link the perception of color to the use of color words in a culture, even to the extent of claiming that colors for which there are no words cannot be perceived (the Sapir-Whorf linguistic relativity hypothesis). Dennett's take on such phenomena is, in many ways, far more radical than this. For Dennett, color is a real property in the world, or, rather, a bewilderingly complex set of properties, but it is a very different set from the property we take it to be (see, e.g., Dennett 1991). However – those properties need to be defined in terms of a class of normal observers. And the fact that such a thing as a class of such normal observers exists at all should take people by surprise – especially

given the (superficial, but compelling) differences between cultures and individuals. What explains the fact that humans, more or less, despite individual and cultural differences, can be shown to be far more similar than they are different in their perceptions of the world? Evolution from common descent is the only non-magical process that can account for these otherwise miraculous facts. However, what processes are going on in each head is not the final word, and this phenomenology is not ineffable or private either. It is, on the contrary, to be understood in terms of representations. But representations of what? And, how are those representations to be compared with one another in ways that preserve our need for them to be truth-valued? Dennett's attempt is to draw these strands together, using a highly nuanced philosophy of mind that is clearly inspired by the metaphysically parsimonious insights of people like Willard Van Orman Quine (his undergraduate tutor, e.g. Quine 1951) and Gilbert Ryle (his PhD adviser at Oxford, e.g. Ryle 1949). This chapter will focus on the major themes of that program, especially those of particular interest to evolutionary scholars.

Content and Consciousness

The classic first essay set to analytic philosophy of mind undergraduates is "What is the mark of the mental?" Various options have been tried over the years but the dominant consensus is that mental states have "intentionality." This is a term of philosophical art that means that mental states are *about* something. What does it mean for a state to be about something? It might represent it in some way, for example. Dennett's position, consistent from his doctoral dissertation, is a form of functionalism: That what minds are is what they do. But, what is it that minds do? Here, there are various possible descriptions. At a bare minimum, minds must enable organisms to make (somewhat) reliable predictions about their ecology and responses to it. Minds inhere in brains. Plants do not need brains (although they can have rudimentary nervous systems) because they do not need to make predictions. Animals over a

certain level of behavioral complexity do need brains. Much of Dennett's earlier work (e.g., Dennett 1969) focused on what might be termed an enlightened behaviorism: A behaviorism that takes seriously a much fuller account of the functional properties of mental states, while still downplaying some of the more grandiose (yet commonsense) assumptions of minds being ineffable or being irreducible private. This sort of *heterophenomenology* (see Dennett 2003) takes the reports of experience seriously as objective facts (which is not to say that the experiences are themselves decisive of what is true). Thus, Dennett hopes to escape the Nagelian problem of how subjectivity can be part of an objective account of the world (see Nagel 1989). More latterly, Dennett (e.g. 2017) has started sketching out in more detail a dual-inheritance model of human evolution: one involving both genes and memes (see below).

The Intentional Stance

Dennett (1983) identifies three independent levels of description. The physical level, coterminous with what Sellars (1963) would call the scientific description, is the most parsimonious level: The level of particle physics. However, no amount of physical description of (say) an organism's trait will reveal its adaptive function: This level of description would be the design stance. Humans, and other organisms, are also steeped in predicting behavior. This requires an ascription of an intentional stance: This type of description takes in folk psychological concepts such as reasons for actions, Gricean (e.g. Grice 1975) accounts of meanings, and is more or less coterminous with a theory of mind (in its broadest sense). Dennett typically refuses to be drawn about the metaphysics of such stances, apparently being satisfied with their mutual irreducibility, and pragmatic requirement for all to be necessary for complete behavioral descriptions. These three levels map closely onto David Marr's (1982) famous distinctions between neurobiological hardware, a (functional) computational level (where this is to be understood in terms of problems solved) and

psychological algorithms. Note also that Tinbergen's (1963) distinctions between four types of biological cause (mechanistic, ontogenic, adaptive, and phylogenetic) while not being identical, can be readily seen as consilient with this way of carving up behavioral descriptions.

Here, and elsewhere, Dennett has shown a knack for "steel-manning": taking his opponents' strongest case onboard, agreeing with it, and then proceeding to show them how they were wrong to think it was an objection. For example, in Dennett (1983) he defends "panglossianism," a term intended to be abusive when first used by Gould and Lewontin (1979) in reference to the adaptationist program. He does this by sketching out precisely such a program for describing behavior at the level of goals, while being noncommittal about the content (or otherwise) of such goals. For example, a thermostat can be said to "want" to keep the temperature at a particular level without any commitment to said thermostat having a conscious state. However, without taking an intentional level description of it, no amount of physical level description will reveal this crucial feature. In a similar vein, he has embraced the "curious inversion of reasoning" (an intended slur on Darwin) that produces design without designers, and competence without comprehension (Dennett 2017).

Research Programs

A good example of the way that theory and practice feed one another in Dennett's work would be to note that his philosophical speculations have often guided psychological enquiry. For instance, the "Beliefs about Beliefs" commentary on Premack and Woodruff (1978) was foundational in generating research into autistic states using the Sally-Anne paradigm. Similarly, a lot of work on change blindness can be attributed to predictions made in *Consciousness Explained* (Dennett 1993).

A Universal Acid

Dennett's first encounter with the theory of Darwinian evolution was when playing bible seller in a theater production of *Inherit the Wind* (the play

about the Scopes Trial) as a teenager. He has been fascinated with it ever since. Evolution by natural selection has been noted as having that effect on people when they realize its implications. Not all scientific theories are on an equal footing. For example, it has been said that if your hypothesis appears to violate the second law of thermodynamics, then you may as well just pack up and go home, it is a nonstarter. In a similar way, evolution by natural selection is so powerfully evidenced by multiply converging lines of independent evidence, using a vast array of differently implemented investigative tools, that if your theory appears to contradict it, then you would be well advised to double-check your working. Some recent philosophers, notably Thomas Nagel (2012), and Jerry Fodor, have fallen foul of this, by attempting to refute evolution by consideration of some conceptual considerations – which usually turn out to be simple misunderstandings on their part. Professional philosophers sometimes make a virtue of not knowing the technical details of a scientific theory or a mathematical theory. Sometimes, this "not seeing the trees of the wood" strategy can work, but it runs the risk of resulting in an *ignoratio elenchi*, such as not appreciating that Xeno's paradox is solved by calculus. Dennett has regularly been seen as a champion of evolutionary theory in this regard. For example, Fodor (2008) states, "Contrary to Darwinism, the theory of natural selection can't explain the distribution of phenotypic traits in biological populations." (p. 11) Dennett's (2008) response is characteristic of his respect for the science over logic-chopping: "Now this really is absurd. Silly absurd. Preposterous. It is conclusions like this, built upon such comically slender stilts, that give philosophy a bad name among many scientists." (p. 25)

Why is evolutionary theory, in particular, something that philosophers are apt to misunderstand? Here is one set of reasons: Philosophy is about drawing of distinctions and this typically boils down to assessing the necessary and/or sufficient conditions for X's being Y's. "What makes these acts, 'acts of justice?'" "What is the correct way to pull the lever on a trolley, when the trolley is heading on tracks towards either five innocent

Kantians, or one really obese consequentialist?”, are typical analytic questions. Philosophers asking these sorts of questions are looking for essences – necessary and sufficient conditions. However, the scientific revolution was largely about replacing essences with processes. A set of key processes are laid out in the theory of evolution by natural selection and these are fatal to essentialist intuitions. An essentialist, like Fodor, asks “What is a species?” and expects to get an answer of necessary and sufficient conditions. Instead, an evolutionist is apt to answer this question with a set of processes with decidedly fuzzy boundaries, such as that species are “Guilds of genotypes committed to free, fair exchange of biochemical technology for parasite exclusion” (Hamilton, 1982). Biology is no friend to those who prefer hard clear conceptual lines.

An example of a more typical analytic problem would be that of the relationship of syntax to semantics. Let us take one example from Dennett’s (1995) Two Black Boxes. This is a thought experiment designed to short-circuit intuitions about whether semantics can ever be framed wholly in terms of syntax, or indeed whether examination of causes can ever elucidate reasons. Dennett’s take on this is that asking *why* questions – what he calls the intentional stance (and what evolutionists readily recognize as adaptive function questions) is unavoidable and that this should alert us to the fact that the problem as usually stated is badly framed, and, further, that only by adopting different descriptive levels will we gain philosophically satisfying solutions.

Why does Dennett hold evolution by natural selection in such high regard, given its propensity to offer fuzzy gradualist solutions to problems, where most philosophers want clear conceptual lines? One reason is that the process is, in his words, a “universal acid.” It takes mysteries of life that might otherwise appear to require divine intervention to account for them, and dissolves them into puzzles that empirical science can explain. The first mystery thus dissolved is the existence of apparent design in the world. Darwin (1859) solved this: The fittedness of organisms to their environments is explained, without the need for a designer, by descent with modification via

natural selection. The second big mystery is morality – not the details of how one should live – but the very existence of altruism. Hamilton (1964) explained this. If his axiomatic extension of natural selection, using genes as the substrate, $rB < C$, is satisfied then altruism can enter into the world. Thus, just in case the relatedness of an organism, multiplied by the benefit accrued by altruistic genes acquired by common descent is greater than the cost, then the behavior can be selected for. And, if altruism can enter, then all human – and other animal – morality can supervene on it. The final mystery to be turned into a puzzle is the human mind. Dennett thinks that this can be solved too, although here he is up against stiffer opposition. He thinks the solution here is also a Darwinian one – that humans evolved to be able to download not genes, but memes. And these semi-autonomous replicating agents use human brains for real estate. Before turning to a consideration of these memes, it is worth considering an example of Dennett’s application of this universal acid to a persistent problem in psychology – explaining how humor arose.

Humor

Why do we have a funny bone? Functions for humor – displaying intelligences, impressing the opposite sex, keeping yourself amused – are not hard to find. However, an *origin* for this ubiquitous sense has eluded scholars. Dennett, prompted by his graduate student Mathew Hurley, and a scholar of the history and philosophy of humor, Reg Admas proposed a fascinating idea, namely, that humor follows the pattern of other enjoyable activities that our genes needed to perform (Hurley et al. 2011). In this vein, it is easy to see why babies are cute, some of the opposite sex is sexy, and that cakes are sweet. But why is humor funny? Or, to put it another way – why has a reward system grown up around this sort of activity at all? Their solution to this is to note that human brains have a particular set of jobs to do that no other organism has to do: Curate incoming information. They would call these “memes” but this is not important at this stage. Humans are trying to drink from conceptual fire hoses of information and have no choice but to leap to

conclusions, and fill in gaps of knowledge and this means that we can make conceptual errors – confusing one thing with another. To triage this process, we require a gatekeeping system that is powerful enough to step in and identify errors in conceptual space. And a reward system for handling this (otherwise) tedious gatekeeping task is the result. In this way, humor is somewhat akin to the opposite of pain. Pain gets us to steer clear; humor gets us to pay attention to those errors, and even to enjoy them so that they do not mislead us. If this account is right, then other factors that might subsequently select for humor (such as finding funny people attractive) can *then* piggyback on this reward system. This account fits neatly with Dennett’s belief that what marks out human beings is their capacity for culture (which is fairly uncontroversial) and this means collections of memes (which is highly controversial).

Memes

Just as genes are packets of instructions for building bodies, memes are understood to be packets of instructions for building minds. Genes express themselves through phenotypes, and some of those phenotypes are more successful than others, leading to differential representation in the next generation. Just as Dawkins (1976) resisted the urge to pin down a gene to a set of necessary and sufficient conditions – leaving it as a replicator with sufficient longevity and power to create phenotypes – so too Dennett is unwilling to be completely nailed down as to what constitutes a meme. What count as memes? Words, certainly. Also snippets of tune, logos, habits that can be acquired, distinct likenesses. In short – something with sufficient longevity to be replicated across brains. Dawkins (1976) first drew on an analogy between the two in *The Selfish Gene*, and Dennett (1993) picked up this particular gage, especially in *Consciousness Explained*, and more recently (2017) in *From Bacteria to Bach and Back*. While the concept of memes has received short shrift in much of the evolutionary literature, work on cultural evolution has continued (see, e.g., Richerson and Boyd 2005). Thus, we have

accounts of evoked culture (Barkow et al. 1995), niche construction, and gene–culture coevolution (see those entries for full details). In short, (almost) everyone is sure that there is something happening besides genes, but the exact ontological status of such a thing is in still in doubt. Are they memes? This is highly controversial, but Dennett’s position is that it does not really matter what we call these elements, but if we accept that something that does the same work is needed for full descriptions then we probably ought to call them something. However, the word *meme* tends to raise defensive hackles in many scientists.

Dennett appears more than happy to respond to these raised hackles. This is probably because he is more than happy to see the connections between levels in scientific explanations, and thus be cognizant of a big picture. Memes, with their somewhat “mushy” associations, raise squeamish responses in those who believe that true reductionist science can only admit the existence of atoms and the void. But atoms and the void are high school physics. Even a cursory glance at quantum mechanics reveals that atoms are not the little billiard balls of high school physics. They are made up of things that can be given full expression in terms of information theory – that is to say, Shannon information. So, is Dennett saying that memes are information in that sense? No, because memes have informational content and Shannon information is content-free. We do not acquire memes per se – although Dennett makes frequent use of computational analogies – such as, memes as “apps” or “thinking tools.” It would be closer to the mark to say that Dennett’s position is not that we get culture – it is more or less that culture gets us. Our big species advantage is to be able to be the hardware for the software that are memes.

Whether this particular program will be fruitful remains to be seen.

Definition

Daniel Nettle’s proposal of a cost and benefit trade-off framework in personality entails that investment toward any personality domain is rarely fully adaptive or costly in the evolutionary paradigm and the optimum personality value is contingent on the varying adaptive problems present in each relevant ecology. Nettle’s contribution to evolutionary personality psychology had since provided researchers a direction toward the development of an evolutionary model of personality.

Introduction

Daniel Nettle’s research spans across a vast range of fields such as health psychology, individual

differences and personality, and evolutionary sciences as well as in topics such as social inequality, cooperation, deprivation, and biological aging. Among these include a series of studies leading up to Nettle's influential paper, "The Evolution of Personality Variation in Humans and Other Animals," which facilitated the progress of the academic study in personality within the evolutionary paradigm. This entry reviews the different theories that have been proposed to explain variations in personality and highlights how Nettle's work has contributed to the field of evolutionary personality psychology.

Explanations for Personality Variation

Since the conceptualization of the five-factor model (FFM), FFM taxonomies have demonstrated strong predictive abilities across various domains such as academic performance (Chamorro-Premuzic and Furnham 2003a, b; Poropat 2009, 2014), work-related performance (Barrick and Mount 1991; Barrick et al. 2001; Salgado 1998; see also Schmitt 2014, for a review), motivation (Judge and Ilies 2002), romantic partnership (Figueredo et al. 2006), and parenting style (Huver et al. 2010). Despite the breadth of its robust application, FFM and other forms of personality taxonomy remain largely descriptive and, by itself, cannot offer any explanation to the origin of personality variation.

Natural Selection

The process of natural selection favors traits that offer evolutionary advantages and creates selective pressure against those that do not. Accordingly, natural selection should eventually remove all but the highest-fitness variant at a particular locus (Fisher 1930; Tooby and Cosmides 1990), creating homogeneity in species-typical traits. Within this natural selection framework, individual differences were thought to originate from random sources and are irrelevant to the basic functioning of the universal psychological machinery – much like the colors of different wires in a car engine – and hence

lacked adaptive significance (Tooby and Cosmides 1990). Variances in traits persist because they are invisible to the selective forces of natural selection – a core proposition of selective neutrality.

Selective Neutrality

Selective neutrality proposes that trait variance results from the accumulation of fitness-neutral mutations, which are mutations that have no net effect on survival or reproductive success, averaged across all environments (Kimura 1983). In this view, being extraverted or introverted would not confer any fitness benefit nor impose any fitness loss on an individual in all environments. However, given the diverse evidence of personality traits influencing fitness-related outcomes such as life expectancy (Chapman et al. 2011), mating and relationship, and health (Ozer and Benet-Martínez 2006), selective neutrality is unlikely to explain the source of differences observed in personality.

Mutation-Selection Balance, Balancing Selection, and Nettle's Trade-Offs

Trait variance is influenced by two opposing forces: one being selection, which reduces variance, and the other being mutation, which increases variance. Since personality traits are consequential to fitness, according to the mutation-selection balance framework, variance in traits is therefore a result of the rate of mutation matching the rate at which natural selection takes place (Keller and Miller 2006; Lande 1975; Zhang and Hill 2005). Humans possess a relatively high mutation load (Eyre-Walker and Keightley 1999), and carrying non-neutral mutations tends to be harmful (Ridley 2000; Tooby and Cosmides 1990). While dominant deleterious mutations are often weeded out by selection, mutations carried by recessive genes persist over time (Zhang and Hill 2005). A mutation load of mostly recessive genes exists in an individual at any point in time (Penke et al. 2007). This mutation load may, therefore, account for the variation observed in fitness-related traits (Keller and Miller 2006; Zhang and Hill 2005) and personality (Lewis 2015; Verweij et al. 2012).

Where both selective neutrality and mutation-selection balance frameworks suggest that trait variance is maintained due to the lack of selective power to eliminate variance (traits either have no fitness impact or that new mutations are continuously introduced), the balancing selection framework postulates a mechanism in which trait variance is selected for (Penke et al. 2007). In this framework, trait variance is maintained when different levels of traits are optimal under different environmental conditions; selective pressures from different physical environments favor different levels of a trait (Buss 2009; Penke et al. 2007).

Nettle's contribution took into account the key pointers of both mutation selection and balancing selection; he recognized mutation as the process that produces differential traits and creates genetic polymorphism; this variance is then maintained by fluctuating environmental conditions (Nettle 2006a, 2011). Expanding on MacDonald's (1995) proposal that any normative range of observed personality variation represents a continuum of viable behavioral strategy, Nettle proposed a framework that alludes the concepts of trade-offs and demonstrates its application to the context of personality with the Big Five.

Origins of Personality and the Big Five

Nettle's approach to personality focuses on the fitness costs and benefits of possessing varying levels of each personality dimension such that these trade-offs shape personality variation. The benefits of possessing a particular trait depend on the adaptive problem the personality trait is designed to solve and how effective this trait is in circumventing the adaptive problem. The cost of a personality trait can arise from the cost intrinsic to the behavioral tendency as a result of possessing the personality trait or from opportunity cost where an individual would have benefitted if the individual had behaved differently.

Agreeableness

Agreeableness refers to the behavioral tendencies characterized by friendliness, consideration, modest

behavior, and propensity for nurturance. Its facets include trust, straightforwardness, altruism, compliances, modesty, and tender-mindedness (Costa and McCrae 1992). High scorers on agreeableness are more likely to be able to empathize with others (Nettle 2007), cooperate and engage in collective action (Denissen and Penke 2008), be accepted by peers and form friendships (Jensen-Campbell et al. 2002), share common resources, and thrive in joint cooperative ventures (Koole et al. 2001). Collectively, these findings seem to suggest that agreeableness serves an adaptive function of forming coalition and alliances that facilitate the cooperative task for the benefit of the collective.

Inasmuch as agreeableness facilitates social exchanges, being agreeable exposes one to social exploitation. Individuals high in agreeableness invest attention in the interests of others, to the detriment of their own, and, therefore, are vulnerable to social exploitation (Judge et al. 2012). When the majority of the population consists of individuals high in agreeableness and cooperation is widespread, cheaters and sociopaths may have considerable advantages to gain through their exploits (Nettle 2011). Hence, based on the trade-off principle, high agreeableness is favored when people live in small isolated groups that demand cooperative effort, whereas low agreeableness is favored when people live in loose social formation or when environment encourages solitary foraging (Nettle 2006b).

This trade-off principle can also be observed in intersexual dimorphism in agreeableness, where women are found to be significantly more agreeable than men (Costa et al. 2001; Schmitt et al. 2008). Women, who bear more childbearing fitness cost than men, often relied on social support and therefore stood to benefit more by better integration into their social network (Campbell 1999). Hence, the fitness benefits women have gained over human's evolutionary history by being agreeable, as opposed to men (Nettle 2011; Nettle and Liddle 2008), have been selected for and maintained.

Conscientiousness

Conscientiousness underlines orderliness, ownership of responsibility, and self-discipline

characterized by the facets of competence, order, dutifulness, achievement-striving, self-discipline, and deliberation (Costa and McCrae 1992). Being conscientious allows individuals in the modern context to excel in academic and work performance (Barrick and Mount 1991). Conscientiousness also enables individuals to delay immediate gratification in favor of longer-term benefits. In our ancestral condition, conscientiousness may benefit individuals facing tasks where adherence to repetitive schedules, forethoughts, or procedures is required to achieve the optimal outcome.

Despite the substantial benefits of high conscientiousness, individuals in the upper limits of conscientiousness incur opportunity cost by forgoing opportunistic situations in favor of their preferred routine. Conscientious individuals, held back by their inhibition and their avoidance of risky sexuality, have less short-term mates (Schmitt 2004). Certain circumstances in our ancestral condition may also be difficult to predict (e.g., unanticipated attack or opportunistic hunting), and failure to seize or act upon these scenarios would have led these individuals to incur fitness costs (i.e., failure to instinctively respond to survival threat or lower food resource; Nettle 2011).

Extraversion

Extraversion refers to the disposition toward social-seeking behavior and is characterized by the facets of warmth, gregariousness, assertiveness, activity, excitement-seeking, and positive emotions (Costa and McCrae 1992). Given extraverts' tendency to seek a variety of social partners, it comes at no surprise that there is a wealth of empirical evidence on the positive association of extraversion with the number of sexual partners (Alvergne et al. 2010; Heaven et al. 2000; Nettle 2005). Extraverts are more likely to engage in polygamy and partner switching, which suggests that there are more opportunities for them to acquire a higher-quality mate than introverts who tend to be more faithful toward a single mate (Nettle 2005). Extroverts are also more likely to initiate social behavior (Buchanan et al. 2005), engage in self-disclosure (Franken-

et al. 1990), and are more physically active (Kirkcaldy and Furnham 1991). On the flip side, in their quest to seek sexual diversity and physical activities, extraverts are more prone to injuries and accidents (Marusic and Musek 2001; Nettle 2005). They are also more likely to incite competitions and conflicts (Lund et al. 2007) and to be involved in criminal activities (Ellis 1987).

Extraversion is a behavioral strategy that is generally risky in nature; individuals with better physical attributes (e.g., attractiveness, formidability, and immunity function) are more likely to be able to bear the cost of an extraversion strategy going wrong (Nettle 2011). Hence, the optimum fitness values of extraversion are more likely to be observed in healthier individuals, an association that Lukaszewski and Roney (2011) support – attractiveness and strength predicted extraversion. Optimum fitness values of extraversion are also dependent on the ecological context. When social structures are fluid and the habitat is unfamiliar, there are considerable benefits to gain by being sociable. Extraversion would enhance group living that would aid survival and facilitate exploratory behaviors, which would allow one to achieve mastery over the new environment. In ecologies where stable and saturated social hierarchies with known environmental hazards exist, it may be more optimal to exercise caution instead (Nettle 2011). The fact that the long allele of the D4DR gene, which is associated with behaviors related to extraversion (Ebstein 2006), is more prominent among nomadic or migratory human populations (Chen et al. 1999) provides evidence to illustrate how the different local ecology produces variance in extraversion by selecting for varying optimum fitness value of extraversion.

Neuroticism

Neuroticism, the tendency to experience negative emotions, is characterized by its facets of anxiety, angry hostility, depression, self-consciousness, impulsiveness, and vulnerability (Costa and McCrae 1992). High neuroticism predisposes individuals to anxiety disorders as neurotic behaviors are manifested as a preventive strategy

that keeps one from facing and challenging their irrational fears from ambiguously threatening stimuli (Lommen et al. 2010). In general, high neuroticism is a risk factor for several psychopathologies, such as depression (Claridge and Davis 2001), schizophrenia (Van Os and Jones 2001), post-traumatic stress disorder (van Zelst et al. 2003), and eating disorders (Cervera et al. 2003). Individuals with high levels of neuroticism tend to experience chronic negative affect, as a result of their less adaptive coping strategies (Gunther et al. 1999), and chronic stress, which subsequently leads to poor physical health, marital instability and dissatisfaction (Kelly and Conley 1987), and sexual dissatisfaction (Fisher and McNulty 2008).

Given the well-detailed literature of the negative outcomes experienced by those high in neuroticism, its prevalence is paradoxical because high neuroticism would have been selected against and yet palpable variation is maintained. According to Nettle (2011), a potential explanation lies in the error management theory (EMT; Haselton and Buss 2000; Haselton and Nettle 2006) wherein the evolved decision-making psychological mechanism is selected to be biased toward the least costly error when the fitness cost of false-positive and false-negative errors was asymmetrical over evolutionary history. When the principle of EMT is applied to explain neuroticism, failure to detect threat in the social (e.g., mate rivalry) or physical environment (e.g., predator) would directly jeopardize reproductive odd and survival. Therefore, it is plausible that in ancestrally high-threat environment, bias toward a false positive (and therefore high neuroticism) is favored, and vice versa (Nettle 2011). High neuroticism in this view serves an adaptive function in threat detection, facilitating vigilance in threatening or competitive environments.

Openness to Experience

Openness, characterized by the cognitive disposition to creativity and aesthetics, comprises the primary facets of fantasy, aesthetics, feelings, actions, ideas, and values (Costa and McCrae 1992). Openness is positively related to artistic creativity (McCrae 1987), and creativity itself is

consequential to fitness as it reflects problem-solving ability. High openness to experience also appears to be a protective factor against age-related cognitive decline (Sharp et al. 2010) and memory impairment in multiple sclerosis (Leavitt et al. 2017). Individuals higher in openness are more actively engaged in cognitively enriching activities, combating decline and impairment with stimulation. Yet, high scorers of openness to experience are also more prone to psychosis and typically have an increased level of paranormal beliefs (McCreery and Claridge 2002; Thalbourne 2000; Thalbourne and Delin 1994), which may implicate fitness costs.

The distinction between the pathological and benign outcome of high openness to experience is not well understood; poets and artist have levels of openness as high as a schizophrenic individual but display no negative symptoms such as anhedonia and social withdrawal (Nettle 2006b). Nettle (2011) speculated that psychotic disorders might be the product of the interaction of a particular cognitive style with adverse general developmental conditions. In this case, openness is not so much selected by the different environment, but rather the optimum fitness value of openness may be contingent on other characteristics of the individual.

Conclusion

At present, although personality psychology has produced successful taxonomies capable of predicting several outcomes, the fundamental question of the origin of personality remains an unsettled science. Nettle's proposal outlined how each individual weights the cost and benefit of a personality strategy, which has fluctuating optimum values based on the local ecology of the individual. The cost and benefit trade-off principle is well supported by the proximate observation in both animals and humans (e.g., Boudreau et al. 2001; Friedman et al. 1995; Haselton and Miller 2006; Jensen-Campbell et al. 2002; Koole et al. 2001; Lukaszewski and Roney 2011; Nettle 2005; O'Steen et al. 2002) and is cited as the core conceptual pillar of recent

personality models (the condition-dependent, adaptationist model of personality; see Lewis 2015). Nettle's overall argument presents itself as a unitary force that brings together seemingly dichotomous concept that extends to the distinction between the genetic and environmental influence of personality.

In the 2011 reiteration of his proposal, Nettle turns toward an additional element in the discussion of cost and benefit trade-off: developmental plasticity. Nettle's case of developmentally induced individual variation is consistent with Buss and Greiling's (1999) concept of early environmental calibration, which states that individuals with a common evolved psychology can experience different development events that channel them into adopting different behavioral strategies. Given that it is not probable for a phenotype to be optimally adaptive in all ecological context and that it is costly to achieve complete plasticity in adulthood (Nettle 2011; Nettle et al. 2013), it is likely that individuals adopt behavioral strategies based on their formative experiences. Developmentally induced variations are either evolutionary responsiveness to specific early environmental cues available during ontogeny to forecast future ecological condition which facilitates the development of phenotypes adaptive in the anticipated ecology or a functional feature of an adaptive response to negative somatic state incurred with early life adversity (Nettle et al. 2013).

In essence, Nettle's framework postulates that each differential trait induced developmentally by environmental conditions has a cost and benefit value that differs cross ecology, and experiential factors funnel development toward a more ecologically beneficial level of a quantitative trait. It is this concept of trade-offs that is central to study of evolutionary personality psychology as it implies that trait variance is selected for; otherwise, natural selection would have selected for a specific value of the trait and reduced personality variance into a species-typical trait. The concept of cost and benefit trade-off in personality presents itself as a viable step toward the advancement of evolutionary personality psychology.

The Middle Ages

Definition

“The Dark Ages” is an historical label used to negatively characterize one period of time by contrasting it with another period, immediately before or after, which is alleged to be superior in some way.

Introduction

The Dark Ages is a label first developed by Renaissance humanists to characterize the Italian past between the fall of Rome and their own day. It has since been adapted to many different places and periods to suit different peoples’ perceptions (Nelson 2007). Wherever located in time, the Dark Ages is rhetorical shorthand variously used to characterize a period as crude, uncultured, barbaric, backward, irrational, violent, or stagnant.

Renaissance Origins

The first use of the term “Dark Ages” to refer to a period of history is usually attributed to the Italian scholar and poet, Francesco Petrarca (1304–1374). Petrarch lamented the political fragmentation of Italy in his lifetime and expressed the view that Italy had been in a state of darkness,

barbarity, and decay since the decline of the Roman Empire (Mommsen 1942). He expressed the hope, however, that a better age might arrive. The renewal of high culture through the careful study of the Classical past would, he believed, help inaugurate that new age. Subsequent generations of humanists adopted Petrarch's view, identifying their own activities with the age of rebirth, or renaissance. In doing so, Petrarch and the humanists adapted an older and essentially religious notion of "light" versus "darkness" to the sphere of culture and created the idea of a dark middle age between the ancient Roman past and their own day.

Reformation and Enlightenment Adaptation

The notion of the medieval period as a Dark Age was subsequently adapted by Protestants in the sixteenth and seventeenth centuries. In this case, however, the darkness was not perceived cultural decline but religious corruption. Reformers, dissatisfied with the state of Christianity in their own period, believed that the purity of the early Christian church had been lost. They attributed the corruption of that original Christianity to changes in the Medieval Latin church, particularly the role of the papacy. It was their belief that religious reform would remedy the corruption, ushering mankind out of the previous Dark Age and into a renewed Christian faith.

Enlightenment thinkers also perceived the period prior to their own as one of darkness, conceived of in their view as a society dominated by superstition and irrationality rather than reason. Writers like Voltaire and Edward Gibbon were broadly, though not uniformly, opposed to organized religion in their own time (McKitterick 2002). As a result, they perceived the medieval period as one of irrationality and zeal for religion, a barbarous Dark Age of credulous faith. This had, in their view, hindered the progress of history and could be remedied by the cultivation of reason. Edward Gibbon, in his *Decline and Fall of the Roman Empire*, attributed the political collapse of the Roman Empire to the spread of Christianity,

which he believed sapped the civic spirit of the Roman people, making them more focused on the afterlife than on the present (Pocock 1976).

Modern Scholarship on the Middle Ages and Late Antiquity

In the late nineteenth century, it was still common to write of the whole period from the decline of the Roman Empire to the Renaissance as "the Dark Ages." However, since then the term has fallen almost completely out of use by practicing historians. This has come about as consensus has built that labeling a period "the Dark Ages" inevitably implies a value judgment, fixing attention only on perceived negatives. "Medieval" and "Middle Ages" are still used by professional historians, because these terms refer more neutrally to a period of time, generally the fall or decline of the Roman Empire and the Renaissance (Robinson 1984). For a time, "the Dark Ages" was retained, but limited to only the Early Middle Ages, the period Edward Gibbon described as the *Decline and Fall of the Roman Empire*. Beginning around the publication of Peter Brown's 1971 *The World of Late Antiquity*, however, scholars have increasingly come to see the period from ca. 300 to 700 CE as a time of change and creative adaptation, rather than collapse and decline (Brown 2013). Thus, the more neutral label "Late Antiquity" has largely replaced "the Dark Ages," even for what used to be perceived as the darkest of the medieval centuries (James 2008).

Conclusion and uses in other areas

Despite these changes among professional historians, "Dark Ages" remains popular as a term of abuse and belittlement, alongside medieval, in popular culture. Policies or actions perceived as backward, irrational, or violent are met with cries that they threaten to bring about a new Dark Age or throw society back into the Dark Ages. Given the religious valence of the September 11 attacks of 2001, the use of "Dark Ages" as a term of condemnation has been given new

impetus, even on opposing political sides. For example, Jill Lepore, in *The New Yorker* in 2013 wrote about the policies of torture and interment characterizing George W. Bush's War on Terror under the heading, "The Dark Ages" (Lepore 2013). On the other hand, writers decry alleged Muslim "extremism" by alleging that Muslims or Islam are stuck in the "Dark Ages," as Julia Hartley-Brewer did in the *Telegraph* in 2015 (Hartley-Brewer 2015).

The Dark Age is also used in some limited contexts in reference to a period marked by the loss of large numbers of records. For example, it has been hypothesized that the possibility that digitally-recorded records might be lost due to changes in physical or electronic format could lead to a "digital dark age." In cosmology, the period between the big bang and the formation of stars is referred to as a Dark Age because it was literally dark. This usage is rarely retained among historians to describe medieval centuries with few surviving documents. However, the massive growth of archaeological study and alternative investigative methods, such as dendrochronology and ice core samples, has shed impressive light on previously invisible periods, rendering their characterization as "dark" obsolete (McCormick 2001).

Charles Darwin's proposed mechanism(s) for the evolution of new species

Introduction

It is evident from the title of Darwin's seminal work that he sought to advance a theory of speciation – that is, to explain the causes and mechanisms of the origin of species. However, many historians of science hold that the question implicit in his title was never fully answered, primarily because he never concretely defined the concept of "species" in the first place and because he conjectured new species likely appeared in sympatry through the process of gradual divergence of characters. The theory of speciation as it is explained in *The Origin* and Darwin's later works is described here in full, and then it is placed in modern context to examine the cases for and against its accuracy and relevance to current evolutionary biology.

Darwin's Explanation of Speciation

Darwin described speciation as the "mystery of mysteries" (1959, p. 1): how do new species

appear? The essence of his answer is that “varieties” turn into new “species.” The specific meanings of these terms have been the subject of much modern debate (for a review see Mallet 2013) because they are used almost interchangeably, or so it seems. Darwin does define them as two nonequivalent but related units, and confusion arises because they are gradations of each other. Varieties are less discrete phenotypic clusters than species are. In other words, “...species are only strongly-marked or well-defined varieties” (1959, p. 55), but there is a degree of ambiguity regarding *when* a variety becomes distinct enough to be called a species: “...the amount of difference considered necessary to give two forms the rank of species is quite indefinite” (ibid., p. 59).

The two keystones of Darwin’s explanation of speciation were the principles of natural selection and divergence. Natural selection is the differential survival of organisms resulting from differences in phenotype: characters better suited to the environment will tend to confer selective advantages to organisms that have them. These characters are therefore more likely to be passed on to the next generation, resulting in evolutionary change in populations over time. Darwin’s principle of divergence holds that sympatric organisms will suffer less from competition with each other if they diverge in character. The interaction of these two principles, and how this results in varieties evolving into distinct species over time, is described in chapter IV of *The Origin*:

Only those variations which are in some way profitable will be preserved or naturally selected. And here the importance ... of divergence of character comes in; for this will generally lead to the most different or divergent variations ... being preserved and accumulated by natural selection. When ... a sufficient amount of variation is supposed to have been accumulated to have formed a fairly well-marked variety, ... [it] would be thought worthy of record in a systematic work. (ibid., p. 117)

In short, natural selection favors variation towards greater divergence. Over time, varieties diverge sufficiently enough from each other to produce distinct gaps in the distribution of phenotypes, warranting their categorization as separate species. Darwin then also draws upon the principle of extinction to explain the absence of

intermediate varieties between species: intermediate phenotypes are less able to compete with more diverged varieties and are driven to extinction. The same fate, for the same reason, awaited “parent-forms” or the ancestral phenotype.

Darwin’s Theory in Modern Context

Modern models of speciation cover two important elements of the process: (1) phylogenetic pattern and (2) barriers to reproduction. Regarding the first, three broad “types” of speciation can be described (see Fig. 1). The first model is of continuous evolutionary change within a population, leading to an ancestral population (A) being replaced, over time, by a new population distinct enough to be classified as a new species (B). In the second, the ancestral population persists, but a new species buds off. In the third, the ancestral form goes extinct and produces two (or more) daughter species (B and C). Darwin’s model of speciation is not easily classified in this framework, because he describes both all models without distinguishing between them explicitly: he conjectures in very general terms that a new variety may diverge from its parental stock and replace it (model 1) or that a new variety can diverge from its ancestral form which persists because the new variety diverges sufficiently from it so that their ecological niches do not overlap (model 2) or that varieties that comprise an ancestral form diverge from each other, outcompeting their parental forms (model 3).

There are four main models describing the degree and nature of reproductive isolation during the process of speciation (see Fig. 2). From most to least isolated, these are allopatric, peripatric, parapatric, and sympatric speciation. In allopatric speciation, extrinsic barriers prevent gene flow between diverging populations. In peripatric, parapatric, and sympatric speciation, incipient species start occupying different niches, and the models differ in the degree to which these populations overlap in physical space. Darwin never explicitly describes the degree or type of isolation he expects to initiate speciation, although he does write that “...I do not doubt

Darwin on Speciation,

Fig. 1 Phylogenetic patterns of speciation. In model 1, the ancestral form (A) evolves into a new form (B) over time. In model 2, the ancestral form persists, and a new species (B) buds off this lineage. In model 3, the ancestral form goes extinct as it splits into two distinct new species (B and C)

Darwin on Speciation, Fig. 2 Types of isolation leading to speciation. Allopatric, or geographic, speciation occurs when an extrinsic barrier prevents gene flow between incipient species. Peripatric and parapatric speciation occurs when some members of an ancestral population begin occupying a new niche: these models differ in the

extent to which these niches and populations' ranges overlap. Sympatric speciation happens in the same area; this can be initiated by a genetic mutation that interferes with reproduction, or gene flow can be interrupted by diverging behaviors or mating strategies

that isolation is of considerable importance in the production of new species" (p. 105). His model is more mechanistic in nature, answering the question of *how* diverging varieties become established enough to be classed as distinct species, but not necessarily what extrinsic factors initiated divergence in the first place.

Darwin's description of speciation is frequently interpreted as an argument for sympatric speciation, and this is the basis of many of Mayr's allegations (e.g., Mayr 1992) that Darwin never

satisfactorily answered the question of the origin of species. Mayr's main point is that evidence for sympatric speciation through divergence is lacking or even absent and that the degree of variation inherently required within a population to supply the raw material for divergence is almost never seen. Consequently, "...intrapopulation variation does not supply the material for a multiplication of species" (ibid., p. 352). Mayr makes the case that allopatric speciation is the norm. Mallet (2008) disagrees with Mayr's criticism

and interprets Darwin as "...discussing the ecology of available niches for populations that have already become somewhat divergent, rather than arguing that the whole process of speciation is necessarily sympatric" (p. 8). Taken together, these views overlap in their interpretation that Darwin does not explicitly concern himself with proximate causes of divergence and rather describes a general process that establishes populations on independent evolutionary trajectories.

Conclusion

Darwin's explanation for the origin of species rests on two key processes: natural selection and divergence of character. He hypothesizes that varieties evolve into new species because natural selection favors divergence of character. This hypothesis is based on the intuitive logic that the more distinct populations are from each other, the less they overlap ecologically and therefore suffer less competition. The ambiguity of his definitions of "variety" and "species," as well as the lack of explicit discussion of proximate causes for initial divergence and consequent implicit argument that speciation occurs sympatrically, has been criticized by modern biologists.

Darwin on the Origin of Language

Definition

Charles Darwin proposed theories of how language emerged. His theories availed for his observations on both animals and humans.

Introduction

In his book, *On the Origin of Species*, Darwin intentionally did not refer to human evolution in detail (Darwin 1859). Although it was perceived that this was a mere oversight, this was not true. Darwin carefully avoided to thoroughly refer to his hypothesis on human evolution because he knew that his theory would not be accepted, but rather it would probably provoke the existing insurmountable opposition. His rivals, however, emphasized the importance of human mind, and language in particular, to compete Darwin's work. Friedrich Max Müller, one of the reputed scholars of that time, was considered as Darwin's most intimidating rival on the linguistic front (Stam

1976). In 1861, Müller delivered lectures at the Royal Institution of Great Britain. These lectures, entitled as “Lectures on the science of language,” were published soon afterward, and Müller used his expertise in the “science of language” as a strong weapon to attack Darwin and Darwinism (Müller 1861). Müller’s hypothesis about the origin of human language in relation to how animals communicate provoked Darwin to further study language.

In 1871, Darwin published his second book *The Descent of Man, and Selection in Relation to Sex*. In this book, he raised the subject of human evolution, and he provided explanation of how language emerged. Darwin’s “musical protolanguage” model was a response to this propaganda and thus represented a combination of comparative data, evolutionary insight, and a biological perspective on language. His innovatory view of language and his models are still astonishingly applicable to contemporary arguments. Darwin proposed a complex model to explain the evolution of language in which he recognized the necessity of various mechanisms in order to produce vocal sounds. Most importantly, he observed that several components in vocal learning shared many biological capacities similar to birds in the production of sound.

Further, Darwin took advantage of a wide comparative collection of data, by using his insight of both nonhuman primate behavior and vertebrates. He proposed a broader theory of evolution that is applicable to insects, flowers, and birds. His purpose was to reveal through investigation general ideas, like sexual selection and shifts of function, to give more information about common and unique human characteristics. Darwin’s model suggested that language emerged only to humans since there is no progression of function between nonhuman primate calls and language (Fitch 2006).

Language as a Natural Aptitude

In his book *The Descent of Man and Selection in Relation to Sex*, Darwin discussed about the evolution of human mind. He suggested that animals have feelings, attention, memory, and

many other mental traits in common with human beings (pp. 34–52). Some of his opponents, however, and specifically Müller had already suggested the hypothesis that animals have memory, experience feelings, and so on. What was of paramount importance, however, was the subtitle “Language” (p. 53) in his book where he spoke for the first time about the evolution of language.

Theoretically, Darwin made some significant observations. First, he acknowledged the essential difference between the biological ability that enables humans to acquire language and specific languages (like Latin or English). Although he initially suggested language as an instinctive propensity shared by all humans, he later emphasized that language is not an instinct provided that every language has to be learnt. He suggested language as natural aptitude whose expression implies that both biological and environmental preconditions must be satisfied.

Second, in spite of the fact he was cognizant of the unique characteristics of the human vocal tract, Darwin supported that the human ability for language must be sought in the brain, rather than the peripheral vocal tract. He concedes that a unique characteristic of humans is the ability to speak fluently and coherently by controlled movements of their lips and tongue (p. 59). Nonetheless he repudiates that simple power of articulation is enough to distinguish human language, since as he explained parrots can talk as well. It is further stated that it is not speech, but humans who are largely capable of joining certain sounds with particular concepts that is definitive of language. This capacity apparently depends on the development of the mental abilities.

Finally, Darwin argued that there is a coherence of the evolution of language to the birdsong, which he thought it was similar to human language. Both humans and birds have fully instinctive calls that they have to learn. Also, he emphasized the fact that both birdsongs and speech form regional dialect depending on their place of residence.

The Musical Protolanguage Model

Darwin’s model of the evolutionary development of the language capacity assumes that various

features of language were obtained in specific order, inspired by unique selection pressures. The hypothetical arrangement that was classified by each addition was called as protolanguages (Hewes 1973). Darwin firstly hypothesized that the evolution of humans progress from an ape-like ancestor to the protohuman cognition. He proposed that some primates developed highly mental capacities even before any form of verbal expression come into use (p. 57). He also stated that both social and technological factors act as drivers of this superior cognitive ability.

Darwin later proposed the musical protolanguage model (Fitch 2006), after observing numerous resemblances in birdsong and human language. He precisely implies that there is an inherent ability to replicate vocals evolved analogously in humans as well as songbirds to express feelings such as love, jealousy, and success. He reasoned that sexual selection is mainly used as the main driver behind the evolution of spoken language.

What is crucial for further investigation, however, is the transition of the musical protolanguage model to a meaningful speech. According to Mithen (2005), the progress of the musical protolanguage model to a meaningful speech remains the greatest explanatory challenge for all musical protolanguage theories. Darwin, however, referred to Müller's writings, and he embraced the theory that language emerged from natural sounds, such as the imitation of the sounds of animals and man's own instinctive cries (Farrar 1870). It is important to note that once the protohumans had the ability to mimic sounds and translate signals into meanings, then the ability to produce speech evolved, including onomatopoeia and the imitation of human emotional vocalizations.

Sign Language

Darwin, in a clear and detailed manner, described the role of gestures in the communication among humans. He was aware of the practice of sign language as a mean of communication to deaf individuals (p. 58). He acknowledged the

importance of gestures in conveying meaning, and he emphasized the fact that in order for people to be able to communicate between them, they must see each other directly. Although he agreed that vocal communication can be aided by signs and gestures (p. 56), he criticized the gestural theorists. In his point of view, the vocal organs were significant to all mammals in the development of communication rather than the use of fingers. A major problem for gestural theories is to explain how such a system evolved from an initially iconic, holistic, meaningful system.

Sexual Selection in the Evolution of Language

Darwin's sexual selection theory states that sexually selected traits develop mostly in men who are considered to be more competitive and only at sexual maturity. Darwin, however, figured out that it is equally developed in males and females and is expressed very early in the biological development (Fitch 2005). There are few explanations to the difficulty that these facts pose. Firstly, during the musical protolanguage stage, sexual selection was the driving force, and song was expressed mainly in males at sexual maturity. After the evolution of language, Fitch (2004) proposed that a selective force appeared to aid women equally express language as men did, and that language develops in earlier stages of life. The communication among the members of the family can be a selective force. Parent's communication with their offspring is an important aspect of their upbringing. Moreover, this can explain the reason language evolves at an early stage in the life of human beings. Language at an early stage of life can help children absorbed their elder's knowledge and experience. Also, this kin-selective force can explain the reason that language evolved only to humans and not to animals. People are going through life stages where they gain knowledge and experience, with very small reproductive output in relation to animals, who can reproduce from their early stage of life (Fitch 2007).

A different approach proposed by Miller (2001) is that sexual selection was an important driving force in human intellectual evolution, including speech. This hypothesis suggests that both sexes can choose and compete for high-quality partners. It is of paramount importance, however, to understand that this hypothesis does not explain the early development of language in infants. Finally, it is considered that sexual selection never played a role in the evolution of language (Miller 2001).

Conclusion

Summarizing the compelling work of Darwin on the origins of language, it is important to note that Darwin proposed that the first step to language evolution was an increase in the mental capacities of humans. He agreed that both social and technological factors are significant in the selective roles. He used a wide comparative collection of data of nonhuman primate behavior and vertebrates, to propose his theories on the evolution of language. Darwin benefits from his studies on animals, and he used his observations to propose his theories on language development. Although he studied both the evolution of human and animals and described many traits shared between them, he concluded that language is unique only to humans.

Darwin's Beliefs

Nicholas Bannan

The University of Western Australia, Perth, WA, Australia

Charles Darwin was born into a family in which both his father, Robert, and his grandfather, Erasmus, were medical practitioners. Erasmus had in addition been a poet and writer on what was then termed “natural philosophy” and whose ideas about evolution anticipated and no doubt influenced his grandson’s perspective. A theme

throughout Darwin's life was the contrast between the religious affiliations of the Darwin line as baptized members of the Church of England and those of the Wedgwood, including Darwin's mother and his eventual wife, Emma, who were Unitarians (Unitarians are egalitarian, protestant Christians who do not believe in the Trinity, but rather in a single divine being). Darwin's mother took him to the Unitarian chapel in Shrewsbury that also provided his initial schooling. She died when Charles was just 8, and Charles went on to the traditional Anglican establishment of Shrewsbury School and an education largely bound up in the Classics.

After the failure of his medical studies at Edinburgh, Darwin was sent by his father to Christ's College, Cambridge, where he attended King's College Chapel regularly due to the superiority of its choral tradition. He was to take a degree in Theology with the intention of becoming a priest. Little sense of calling was involved in this pragmatic decision, and there was no anticipation that Charles's studies would lead to a lifetime investigating the natural world. Indeed, "scientist" was barely a profession in the early nineteenth century, and most practitioners of the branches of science that Darwin encountered at Cambridge and elsewhere who influenced his initial career were themselves clergymen: notably William Paley, William Whewell, and John Henslow. Indeed, Whewell coined the term "scientist" in 1834 to denote the practitioner who relied on experimentation, measurement, and observation rather than abstraction – what we now call "evidence-based" science as opposed to "natural philosophy." Nevertheless, the new findings arising from the application of scientific method in geology placed a strain on thinkers whose world view needed to remain consistent with the faith they preached. Biblical accounts such as The Flood and other cataclysmic events influenced a trend in geology embraced by Whewell and his followers. They were dubbed *catastrophists* and were opposed to *uniformatarians* (note the implied link to the religious denomination) such as the leading geologist Charles Lyell, whose viewpoint was that the same forces acted interdependently on the earth over long periods of time (Ruse 2007, 3). Darwin

eventually sided with Lyell, taking the first volume of his mentor's *Principles of Geology* with him on the *Beagle* voyage. Application of Lyell's work to the phenomena he observed, especially in the Pacific, led to one of Charles's earliest scientific publications, on the formation of coral reefs (Darwin 1842).

The *Beagle* voyage had for the young Darwin many of the attributes we would now associate with postgraduate study. It involved scientific observation, exploration, and travel, permitting the examination of geological features, flora, and fauna as well as contact with people from markedly different cultures and environments to those Darwin would previously have encountered. The *Beagle* was Charles's graduate school, a community of scholars in which ideas were discussed and samples obtained for later analysis, while favored reading matter embraced both Lyell's geology and Milton's *Paradise Lost*. Above all, the *Beagle* voyage led both to immediate publication of the edited ship's journal (Darwin et al. 1839) and to the sequence of articles on coral, volcanic islands, and barnacles that would pave the way for *The Origin of Species* and for Darwin's eventual confidence to share its radical implications.

Almost immediately on his return from the *Beagle* voyage, alongside the preparation of publications and analyses of the copious and ground-breaking data he and his colleagues had assembled, Darwin initiated what was to become a parallel project, the systematic planning of family life: in short, his marriage prospects. He set out a list of the arguments for and against and the criteria that a suitable partner would furnish. While living like a hermit might provide the circumstances in which hard work could be achieved, he would miss companionship, music, and children (Darwin 1838). The woman whom Darwin, on deciding to marry, pursued was his first cousin, Emma Wedgwood.

Emma combined the fun-loving accomplishments of a young woman of her time, provided for her by her rich family, with a deep commitment to the Unitarian faith. She was a proficient linguist, well-traveled within the European cultural orbit that enabled her to take piano lessons from Chopin and Moscheles (Healey 2010). They

became engaged in November 1838 and wed just 2 months later. The marriage secured Darwin's financial status as well as providing him with the lifelong support that, as a virtual invalid, his considerable achievements were to depend upon.

When children came, the Darwins proved to be tolerant and active parents, sharing their interests and accomplishments. While the Bible was read at family prayers, and Emma remained true to her Unitarian upbringing, the children were baptized in the Church of England and attended the little parish church of the country home they established at Downe in Kent (Healey 2010, 199). The children followed their mother's Unitarian example in refusing to turn to face the altar during recitation of the creed (Keynes 2001, 115). Within Down House, they made music, like their mother, and went on to help their father with his experiments. But Charles himself participated less in their religious life and by his own account had ceased to believe in God by 1849: "disbelief crept over me at a very slow rate, but was at last complete" (Darwin 1969, 86). Despite reading a variety of recent interpretations of the Bible and its sources, he felt that the claims of Christianity were not supported by the evidence (Keynes 2001, 120). By contrast, his meticulous dissection and examination of living and fossil species was, at a similarly cumulative rate, convincing him of an alternative theory of creation.

The death from tuberculosis in 1851 of his daughter Annie at the age of just 10 came as a hammerblow. A week later, Darwin wrote a brief account of her life "as I think in after years, if we live, the impressions now put down will recall more vividly her chief characteristics" (Darwin 1985, 5.540–542). The eulogy movingly combines the expression of grief of the bereaved father with the scientific detachment and attempt to capture detail of the observant naturalist:

Her figure and appearance were clearly influenced by her character: her eyes sparkled brightly; she often smiled; her step was elastic and firm; she held herself upright, and often threw her head a little backwards, as if she defied the world in her joyousness. For her age she was very tall, not thin, and strong. Her hair was a nice brown and long; her complexion slightly brown; eyes dark grey; her teeth large and white. (ibid)

So began the decade that was to culminate in the publication of *The Origin of Species* in 1859. The long gestation of the work related partly to its sheer scale, representing the need to leave no available stone unturned in presenting an argument Darwin knew to be contentious. Darwin was conscious, too, of the impact on his wife and the believers among his circle of friends and relatives. *The Origin* barely mentions human evolution, let alone the interpretation of evidence for proposing it: this would emerge in his later work.

The eventual conceptual framework out of which the clarity of *The Origin of Species* emerged owed as much to the influence of farmers, pet breeders, and agriculturists as to biological theorists. The artificial selection they practiced provided a key insight into the potential of Darwin's theory of natural selection. Ever a practical man himself, capable of designing and building his own experimental resources in the garden of Down House, Darwin saw in the domestication of plants and animals a mechanism traceable in the natural world as species became shaped by the changing forces Lyell's geology revealed. Relating this to geographical distribution, as in the case of the Galapagos turtles and the finches whose unique characteristics were discerned in his laboratory by the ornithologist John Gould, enhanced the sense that speciation developed over time as organisms interacted with a particular environment. The mathematical model provided by Thomas Malthus – another Anglican clergyman – illustrated the means by which adaptation would favor the survival of those most fitted to their environment at the expense of the surplus it could not support (Ruse 2007, 9).

The theory of evolution – descent by modification – thus came to Darwin in a manner that paralleled the publication practice of contemporary novels by authors such as Dickens, whereby chapters appeared serially in magazines and the plot unraveled step by step: there was no opportunity to "look ahead" to future installments. Darwin and his closest circle were increasingly aware of the implications of his work but unsure of the impact of its dissemination. But science was beginning to replace religion in demonstrating ultimate causality (Ruse 2007, 9), and Darwin's

careful assembly of facts and cumulative argument were in danger of being gazumped by a journalistic whodunnit such as the 1844 publication on evolution by Robert Chambers. The more convincing and robust submission Darwin received from Alfred Russel Wallace in 1858 was what clinched matters, and Darwin shared with Wallace priority in the publication of the theory of natural selection.

As is widely known, the outcome was a counterblast from religionists, setting in motion the contrasting positions of science and creationism that continue to divide education and society in our own time. The model for this debate was the famous confrontation at Oxford between Bishop “Soapy Sam” Wilberforce and Darwin’s outspoken apologist Thomas Huxley. What is less well known is that Wilberforce (1860) had read the book in detail and brought out an extended review with Darwin’s own publisher, John Murray. The catalyst for Huxley’s withering condemnation was precisely that Wilberforce resorted to populist rhetoric in attempting to sway an audience less acquainted with what Darwin had actually written.

But the shorthand for Darwin’s theory, which we are descended from apes, became the principal image through which Darwin’s argument would be summarized. Benjamin Disraeli drew on this in a speech of his own in Oxford in 1863. As a Jew and thus a social outsider aspiring to high office within the traditionally closed community of the Tory party, Disraeli needed to position himself carefully in the eyes of the Bishops and the prevailing Anglican ethos of the two ancient universities. His own trope on Wilberforce’s remark was: “My Lord, I am on the side of the Angels” (Blake 1966, 505), an image later captured by the cartoonist Lalla Rookh (1874) with the caption *Paradise and the Peri*.

A social equivalent to the political competitiveness with which Disraeli had to contend is another common inference of Darwin’s theory of natural selection, one that conceals its author’s own personal interest in the relationship revealed in his later writing between human evolution and altruism. Spencer (1885) and Galton (1883) extrapolated versions of evolutionary thinking consistent with “survival of the fittest” –

Tennyson’s (1850) “nature red in tooth and claw” – and an interpretation applicable to ideas of social competition that in Galton’s case led to eugenics. By contrast, Darwin himself took a considerable interest in charitable work and the welfare of those less fortunate than himself, as well as in the cultures of the people of many different people he met on the *Beagle* voyage. His personal conscience aligned with that of his Wedgwood relatives’ strong stance against slavery, epitomized in the pottery cameo depicting a kneeling slave in chains with the slogan “Am I not a man and brother?” An indication of the enlightened political assumptions of the mature Darwin would be his organization of a letter arguing the need for political representation in South Africa to recognize the involvement of every citizen “without regard to color or race” (Darwin et al. 1877).

Darwin’s wide interests in several disciplines, both scientific and artistic, conferred the capacity for keen observation rendered in expressive language. His penchant for innovative connection permitted the imaginative leaps that exemplified his approach to the natural world, subsequently explained through carefully deduced logic. His liberation into religious “freethinking,” first through Unitarianism, thence agnosticism, and finally atheism, is inseparable from his questioning of prevailing authority. An example would be his noting of similarities in the appearance on the shoreline of sedimentary rocks in Tasmania and Tierra del Fuego, anticipating tectonic drift some 50 years prior to Wegener (Banks and Leaman 1999). Fittingly, his son George Darwin (1879) proposed on mathematical grounds the geological origins of the tides and their relationship with the moon; another son, Francis, went on to a Professorship in Botany while also pursuing a second career as a performer on historic wind instruments (Darwin 1914).

Darwin’s journey, from acceptance that his studies at Cambridge would lead to a life as a country parson to his becoming the leading scientist of his age and an icon of non-belief in divine creation, has left a legacy that resonates in evolutionary psychology today. His mentor William Paley’s presentation of the “argument from design” set up the conditions for which Darwin’s work provides the alternative. Paley (1802) asked

the reader to imagine the difference between encountering a stone while walking in the country and finding a watch on the ground. The latter requires us to accept that it:

... must have had a maker: that there must have existed, at some time, and at some place or other, an artificer or artificers, who formed it for the purpose which we find it actually to answer; who comprehended its construction, and designed its use. (Paley 1802, 6)

Paley's application of this conclusion to every complex structure in the natural world remains the basis of creationist argument in our own time and provided Richard Dawkins with the title *The Blind Watchmaker* (1986) of his guide to acceptance of the issue: "Darwin and Wallace solved it" (Dawkins 1986, xiii).

Two ironies emerge from the biographical and epistemological stories that are bound up in Darwin's legacy. The first is that the science of evolutionary psychology that descends from his theories of natural and sexual selection fully embraces a place for religion in the cultural development of *Homo sapiens*. The role of religion and the adaptive nature of spirituality inform work in the human sciences, art, music, and literature (Tylor 1871; Jung 1966; Lévi-Strauss 1966; Mithen 1996; Boyer 2001; Atran 2004; Pamcutt 2009; Lewis-Williams 2010). From an anthropological perspective, there need be no incompatibility between the application of evolutionary thinking and exploration of the origin and purpose of religion.

The second irony is that, contrary to his family's wish for Darwin to be buried in the country churchyard of his home, the public and political response to his passing favored his being laid to rest in Westminster Abbey with the full honors the state religion could afford (Ruse 2007, 2). There he lies, next to Isaac Newton, commemorated in a manner fitting to the scale of his achievement, if confusing to those who assume him to be an imposter in God's house.

Darwin's Education

Nicholas Bannan
The University of Western Australia,
Perth, WA, Australia

Darwin's education, both at school and university, appears from a modern perspective to be surprisingly lacking in focused preparation for the scientific achievements that lay ahead of him. However, both his father and grandfather trained and practiced as doctors, and it was initially assumed that Charles would follow in their footsteps. His grandfather, Erasmus Darwin, combined his medical duties with philosophical and literary writings, including the two-volume *Zoonomia; or the Laws of Organic Life* (1794)

that embraced speculations about the evolution of life which must have been known to his grandson.

But education in the early nineteenth century largely comprised, in addition to mathematics, the translation and exegesis of Classical and biblical texts. Natural science, if studied at all, was engaged in a spirit of respect for the traditions of Greek philosophy and scriptural precedent. Attendance at church or chapel was as important as attendance at school, if a little less regular. Thus Darwin's earliest experiences included being taken by his mother to the Unitarian Chapel in Shrewsbury, though his mother died in 1817 when he was just eight, and he reported having very few memories of their time together, with the exception of a recollection of her, black-gowned, on her death-bed. Darwin's father thus brought up his young family as a widower, and proved a positive and respected influence on his son despite initial exasperation at the young Charles's apparent waywardness.

Lacking a mother, Charles developed a very close relationship with his older brother Erasmus, named for their grandfather. Five years older than Charles, Erasmus was the initially successful brother who followed the family tradition of studying medicine at Edinburgh and Cambridge and pursuing a career as a doctor. Charles later recalled Erasmus's influence with affection, including his leading chemistry experiments they set up together in the tool-house of their garden in Shrewsbury:

My brother Erasmus possessed a remarkably clear mind with extensive and diversified tastes and knowledge in literature, art, and even in science. For a short time, he collected and dried plants, and during a somewhat longer time experimented in chemistry ... He read much, even whilst a boy, and at school encouraged me to read, lending me books. (Darwin 1887, p. 12)

Charles first attended (1817–1818) a Unitarian day-school run by the Rev. G. Case, minister of the chapel that his mother had attended before her death. He later recalled: "I have been told that I was much slower in learning than my younger sister Catherine, and I believe that I was in many ways a naughty boy" (Darwin 1887, p.14).

Unitarianism was the denomination of his mother's Wedgwood branch of the family,

connection with which Charles was later to reestablish through marrying his first cousin, Emma. After his mother's death, Charles and Erasmus were baptized into the Church of England, possibly in order to remove some of the barriers to their future education that at that time nonconformism posed. The brothers went on to Shrewsbury School, one of England's august and historic private academies. Charles attended the school 1818–1825.

Charles's impressions of Shrewsbury School are vividly captured in his own words:

Nothing could have been worse for the development of my mind than Dr. Butler's school, as it was strictly classical, nothing else being taught, except a little ancient geography and history. The school as a means of education to me was simply a blank. During my whole life I have been singularly incapable of mastering any language. Especial attention was paid to verse-making, and this I could never do well. I had many friends, and got together a good collection of old verses, which by patching together, sometimes aided by other boys, I could work into any subject. Much attention was paid to learning by heart the lessons of the previous day; this I could effect with great facility, learning forty or fifty lines of Virgil or Homer, whilst I was in morning chapel; but this exercise was utterly useless, for every verse was forgotten in forty-eight hours. I was not idle, and with the exception of versification, generally worked conscientiously at my classics, not using cribs. The sole pleasure I ever received from such studies, was from some of the odes of Horace, which I admired greatly.

When I left the school I was for my age neither high nor low in it; and I believe that I was considered by all my masters and by my father as a very ordinary boy, rather below the common standard in intellect. To my deep mortification my father once said to me, "You care for nothing but shooting, dogs, and rat-catching, and you will be a disgrace to yourself and all your family." But my father, who was the kindest man I ever knew and whose memory I love with all my heart, must have been angry and somewhat unjust when he used such words. (Darwin, in Darwin 1887, p. 16)

At the age of only 16, in 1825, Darwin's father arranged for Charles to be admitted to Edinburgh University to study medicine. But the pursuit of medicine not to his liking: "The instruction at Edinburgh was altogether by lectures, and these were intolerably dull" (Darwin 1887, p. 17). After just 2 years of somewhat unfocussed studies

in Edinburgh, Charles transferred to Christ's College, Cambridge, with the assumption that he would prepare to become a vicar. Such a plan was by no means incompatible with his growing interest in natural history: some of the foremost natural scientists of the preceding generation and in his day, including Gilbert White, William Paley, William Whewell, and John Henslow, were ordained priests of the Church of England. All were to prove influential on the early career of Charles Darwin.

Time at Cambridge included attendance at Evensong in King's College Chapel and other musical events: "This gave me intense pleasure, so that my backbone would sometimes shiver" (Darwin 1887, p. 22). Darwin's interest in choral music was recalled with enthusiasm by his friend John Herbert, who was to present the young explorer with the microscope that served him so well on the *Beagle* voyage (Herbert 1832). Music was, by his own account (Darwin 1838; Stott 2003, pp. 75–76), to play a significant part in his choice of the pianist Emma Wedgwood as his wife. A clearer influence on Charles's future emergence as a scientist were the geology and botany field trips through which the hunter of his father's dismissive description began to acquire the observational skills and knowledge that were to serve him as an explorer. The process of Darwin's transformation into a serious scholar was nevertheless not immediate:

I was so sickened with lectures at Edinburgh that I did not even attend Sedgwick's eloquent and interesting lectures. Had I done so I should probably have become a geologist earlier than I did. I attended, however, Henslow's lectures on Botany, and liked them much for their extreme clearness, and the admirable illustrations[.] (Darwin 1887, p. 22)

The outdoor experiences that supplemented the dullness of the lecture theatre were what captured Darwin's imagination:

Henslow used to take his pupils, including several of the older members of the University, field excursions, on foot or in coaches, to distant places, or in a barge down the river, and lectured on the rarer plants and animals which were observed. These excursions were delightful. (Darwin 1887, p. 22)

Geological exploration under the guidance of Sedgwick was to follow, including a bracing trip to the mountains of North Wales.

The move towards a scientific focus commenced with small steps: "... no pursuit at Cambridge was followed with nearly so much eagerness or gave me so much pleasure as collecting beetles" (ibid.). The commitment to a scientific future essential to Darwin's selection for inclusion in the *Beagle* voyage began to take shape:

During my last year at Cambridge, I read with care and profound interest Humboldt's "Personal Narrative." This work, and Sir J. Herschel's "Introduction to the Study of Natural Philosophy," stirred up in me a burning zeal to add even the most humble contribution to the noble structure of Natural Science. No one or a dozen other books influenced me nearly so much as these two. (Darwin 1887, p. 24)

It was Henslow who made the initial connection that led to Darwin's opportunity to join the *Beagle* voyage as gentleman companion to the ship's captain, Fitz-Roy. The postgraduate pathway for a scientist was an uncertain one, probably to be followed in an amateur fashion alongside the study of Divinity. No such dedicated career path being available to him, the *Beagle* voyage could be viewed as Darwin's doctorate and post-doc rolled into one, both resulting in the opportunity to publish his immediate response to the encounters of the 5-year voyage and representing the basis for his lifetime's achievements in several fields.

Darwin's Struggle for Life

Antonello La Vergata

Dipartimento di Studi Linguistici e Culturali,
Università degli studi di Modena e Reggio Emilia,
Modena, Italy

"Struggle for life" appears in the title of Darwin's epoch-making book, *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* (1859). However, Darwin also used "struggle for existence" in this and other writings. Both were used "in a large and metaphorical sense, including dependence of one being on another, and including (which is more important) not only the life of the individual, but success in leaving progeny." Darwin's examples were clear:

"Two canine animals, in a time of dearth, may be truly said to struggle with each other which shall get food and live. But a plant on the edge of a dearth is said to struggle for life against the drought, though more properly it should be said to be dependent on the moisture. A plant which annually produces a thousand seeds, of which only one of an average comes to maturity, may be more truly said to struggle with the plants of the same and other kinds which already clothe the ground. The mistletoe is dependent on the apple and a few other trees, but can only in a far-fetched sense be said to struggle with these trees, for, if too many of these parasites grow on the same tree, it languishes and die. But

several seedling mistletoes, growing close together on the same branch, may more truly be said to struggle with each other. As the mistletoe is disseminated by birds, its existence depends on them; and it may metaphorically be said to struggle with other fruit-bearing plants, in tempting the birds to devour and thus disseminate its seeds. In these several senses, which pass into each other, I use for convenience sake the general term of Struggle for existence”.

Darwin then acknowledged his debt to the economist Thomas Robert Malthus' theory of human population growth inevitably pressing on the means of subsistence:

“A struggle for existence inevitably follows from the high rate at which all organic beings tend to increase [...] As more individuals are produced than can possibly survive, there must in every case be a struggle for existence, either one individual with another of the same species, or with individuals of distinct species, or with the physical conditions of life. It is the doctrine of Malthus applied with manifold force to the whole animal and vegetable kingdom; for in this case there can be no artificial increase of food, and no prudential restraint from marriage” (Darwin 1859, pp. 62–63).

Darwin's reading in Autumn 1838 of the 1826 edition of Malthus' *Essay on the Principle of Population* was a decisive step towards his theory of natural selection. Also Alfred Russel Wallace referred to Malthus as a source of inspiration for the theory of evolution he exposed in his essay “On the tendency of varieties to depart indefinitely from the original type” (Wallace 1858), a theory which impressed Darwin as bearing striking similarities to his own (but was not exactly the same: see Gayon 1998).

Words such as “struggle,” “battle,” and “war” had long been used when speaking of nature and human life, and were not uncommon in British social and political debates in the years before Darwin published his theory (Gale 1972). The philosopher and sociologist Herbert Spencer, who was to become the most popular philosopher of evolution of the late nineteenth century (and who later coined the phrase “survival of the fittest,” which Darwin adopted as equivalent to “natural selection”), described nature as pervaded by a “stern but beneficent discipline” preserving the species types by eliminating weak and unhealthy

individuals. He hoped that society would follow the same course, and that the improvident, lazy, and unable would be left unprotected by the State in a free-for-all competition (Spencer 1851).

By “war of nature” and similar expression, pre-Darwinian naturalists generally meant interspecific struggle, that is struggle between different species. Those who also considered intraspecific struggle, that is struggle between individuals of the same species, saw it as a factor of conservation, rather than transformation, of the species type: variations that were not “true” to it were eliminated (La Vergata 1990). By extending the meaning of “struggle,” Darwin emphasized the intricate network of relations between organic beings and between them and their environment, both physical and, above all, organic. This was the context in which natural selection operated, eliminating some forms while preserving others and favoring the accumulation of useful modifications along divergent branches. The most vocal supporter of Darwin in Germany, Ernst Haeckel, had exactly “all those complex interactions (*Wechselbeziehungen*) that Darwin indicates as the conditions of the struggle for life (*Kampf um's Dasein*)” in mind when he coined the word “ecology” in 1866 (Haeckel 1866: vol. I, 8, note; vol. II, 235–236, 286–287; 1878, p. 17).

Darwin's struggle for life ran contrary to the belief that a providential harmony, although ensured by apparently cruel means, reigned in the economy of nature, a view that had found its most well-known expression in the Swedish naturalist Carl Linnaeus. At the end of the *Origin*, Darwin warned the reader lest he forget that behind the beautiful scenery of a “tangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth,” there raged “the war of nature, [...] famine and dearth,” from which “the most exalted object which we are capable of conceiving, namely, the production of the higher animals, directly follows” (1859, pp. 489–490).

Being an anthropomorphic metaphor, the struggle for life was easy to transfer (or re-transfer) to human affairs and to apply to social and political discourse. Darwin himself

used the phrase in the pages of *The Descent of Man, and Selection and Relation to Sex* (1871) in which he dealt with human races and “natural selection in civilized nations,” for instance, to explain the success of white colonizers all over the world (and of English colonizers of Canada over the French), and the decadence of nations and races which were “left behind in the struggle.”

Application of the struggle for life to individuals within society and/or to nations or races (the two terms were often used interchangeably) was a key element of the very complex phenomenon called “social Darwinism.” There were many, even contrasting varieties of it: individualistic, nationalistic, racist, even socialistic, depending on political biases and on which level of the struggle each author considered crucial for the progress of mankind. Others, however, appealed to Darwin’s own theory, in *The Descent of Man* (1871), on the origin of human morality in the social instincts of animals. They argued that mutual aid and cooperation were much more important factors in evolution, animal as well as human, than rivalry and aggression. The most well-known of these authors was the Russian anarchist Pëtr Alekseevič Kropotkin, who in his *Mutual Aid* (1904) rejected the description of nature as a “gladiatorial show,” to use the words of Thomas Henry Huxley (1888), Darwin’s main supporter in Britain. Anti-individualistic interpretations of the struggle for life became popular among socialists, especially in Germany and Russia (Kelly 1981; Todes 1989). In France, the idea prevailed that struggle did play a role in evolution, but it took place not between individuals but between groups of organisms and their environment – an “*association pour la lutte*” against adverse conditions, as the biologist and politician Jean-Louis de Lanessan (1881) called it. Most French biologists disliked Darwin’s natural selection acting on “spontaneous,” or “chance,” variations and preferred to think that the environment directly induced inheritable adaptations.

Karl Marx and Friedrich Engels criticized Darwin’s struggle for life on the grounds that it was imbued with class ideology. They praised Darwin for giving “the death blow to teleology”

but reproached him for accepting Malthus’ doctrine, which they hated. Writing to Engels in 1862, Marx found it “amusing” and “astonishing” how “Darwin recognises among beasts and plants his English society with its division of labour, competition, opening up of new markets, ‘inventions’ and the Malthusian ‘struggle for existence’ (*Kampf ums Dasein*).” “It is” – he went on to say – “Hobbes’ *bellum omnium contra omnes*, and it reminds one of Hegel’s *Phaenomenology [of Mind]*, where bourgeois society features as ‘the spiritual animal kingdom’, whereas in Darwin it is the animal kingdom that features as the bourgeois society.” Engels agreed: “Darwin did not know what bitter satire of people and particularly his fellow countrymen he was writing when he showed that the free competition and the struggle for life, which economists celebrate as the highest historical achievement is the normal condition of animal life.” Marx ridiculed the “ignorance and intellectual laziness” of those who claimed “to subsume the whole history under one great law of nature” – that is, struggle for life used as a “mere phrase” – “instead of analysing how the struggle for life manifests itself historically in different, particular forms of society.” Engels criticized the “infantile trick” by which the bourgeois view of society was first transferred by Darwin into the natural world and then re-transferred to society by bourgeois ideologists. “In this case” – he added – “the struggle for life merely consists in the productive class taking on the direction of production and from the hands of the class to which it has so far been entrusted, but which has by now become incapable to do it; and this means the socialist revolution” (Marx and Engels 1956-: vol. 30, pp. 249, 324; vol. 32, pp. 685–686; vol. 34, p. 170).

“Struggle for existence” and the like became popular catchphrases, and many biologists themselves ignored Darwin’s warning and took them in the most narrowly literal sense. For instance, the French physiologist, pioneer of serotherapy and eugenicist Charles Richet, Nobel prize winner for 1913, repeatedly wrote that in the “*combat pour l’existence*,” an “unceasing, relentless, merciless fight,” victory went to “the most able, the best armed, the most

numerous,” to wit, the “strongest,” that is the “best.” “Those that succumb deserve to succumb,” as “their inferiority explains, justifies and legitimises their being crushed.” A “primordial law dominates nature,” by which “the strong annihilate the weak, and the big eat the small;” it exacts “fratricidal struggles, ruthless fights, prey eaten alive, slaughter, massacre, suffering, illness, famine, savage death.” Richet believed that an “endeavour after life” (*effort vers la vie*) was the essence of the living being and the main cause of evolution and of “constant progress” (La Vergata 2018).

Especially in Protestant countries, Darwin's struggle for life was seen as further, decisive evidence and scientific confirmation that nature ensured progress – physical, moral, and spiritual – through overall strife, effort, endeavor, and self-help. It was generally believed that there was a continuity between biological evolution and human progress. However, it was also generally agreed that in the course of human evolution, the literal struggle for life slowly but increasingly took on the form of a competition of ideas, abilities, habits, and customs. Some went as far as saying that the meaning of the entire process lay in the “ascent of man” from a primordial hell to refined spirituality culminating in the “struggle for the life of others” (Drummond 1894), or in the triumph of “evolutionary love” (Geddes and Thomson 1889). But nature's lesson was clear: life must be strenuous (Thomson 1909).

The catastrophe of the Great War put an end to the equation of evolution and progress through struggle. The development of population genetics and the synthesis of Darwinism and Mendelism in the 1930s and 1940s, as it were, de-literalized and de-Malthusianized the struggle for existence by reformulating fitness in terms of gene frequencies and differential survival of variations. The struggle was, generally speaking, no longer considered as a cause of natural selection. Natural selection occurred whether or not resources were scarce. What mattered was that there were differences of fitness within a population (Gayon 1998; Radick 2003). The development of ecology, and the subsequent rethinking of competition and cooperation among organisms, did the rest.

Definition

An evolutionary hypothesis for the culinary use of spices based on their antimicrobial properties.

Introduction

In their 1999 article, Paul W. Sherman and Jennifer Billing summarize their findings on the global patterns of spice use by humans and how country and regional differences in spice use may provide support for the hypothesis that, ultimately, spices are used to reduce foodborne illness and food poisoning.

The article is an extension of a review published in 1998 (Billing and Sherman 1998). It starts with a brief definition of *spice*, which is not a botanical category but a culinary term used to refer to various plant products sourced from different types of woody shrubs and vines, trees,

aromatic lichens, and roots, flowers, seeds, and fruits of herbaceous plants. Next, based on a survey of traditional cookbooks (93 books from 36 countries), the authors report the patterns of spice use in 4578 meat-based recipes across the globe. Vegetable-based recipes were less frequent in the sampled cookbooks and significantly less spicy than meat-based recipes (Sherman and Hash 2001). Finally, the authors show how differences in patterns of spice use between countries and within countries are correlated to temperature and may serve as evidence for their evolutionary explanation for this culinary practice. In addition to their obvious effect on food flavor, color, and palatability – the proximate explanation for the use of spices – the authors put forward an ultimate explanation based on the properties of the phytochemicals found in spices.

The Antimicrobial Hypothesis

Most of the “secondary compounds” found in spices are part of the defense repertoire of plants against predators, parasites, and other biological enemies. Since many of these, like bacteria and fungi, also attack meat and other food items, Sherman and Billing suggest that humans use spices to prevent foodborne illnesses and food poisoning. To support their antimicrobial hypothesis, the authors then present the evidence to satisfy five predictions:

Prediction 1: *Spices should exhibit antibacterial and antifungal activity.* Phytochemicals extracted from spices have been amply tested. All 30 spices – for which laboratory test results were available – killed/inhibited at least 25% of the bacterial species on which they were tested. Half of the spices tested killed/inhibited at least 75% of bacterial species, and four spices (garlic, onion, allspice, and oregano) killed every bacterium tested.

Prediction 2: *Use of spices should be greatest in hot climates, where unrefrigerated foods spoil especially quickly.* Considering all 36 countries sampled, mean annual temperature ranged from 2.8 °C to 27.6 °C (37.04–81.68 °F).

Within this range, as average temperatures increased among countries, significant increases were found in the proportion of recipes that called for at least one spice, the mean number of spices per recipe, and the number of different spices. Significant increases were also found when considering only spices with high inhibitory activity ($\geq 75\%$ bacterial activity inhibited).

Prediction 3: *A greater proportion of the bacteria should be inhibited by recipes from hot climates than from cool climates.* The mean proportion of traditional meat-based recipes that called for each highly inhibitory spice increases as mean annual temperatures increase. A positive significant correlation was also found between the number of bacterial species inhibited by each spice and the number of countries that use that spice. Although data on the local assembly of bacterial species of each country were not available, when considering 30 widespread bacterial species, the fraction of food spoilage bacteria inhibited by the spices used in each country also increased significantly in hotter climates.

Prediction 4: *Within a country, cuisine from high latitudes and elevations (i.e., cooler climates) should contain fewer and less potent spices than cuisine from lower latitudes and elevations.* Limited evidence was found for this prediction since regional cookbooks were available only for China and the United States. However, in both countries the total number of spices used, the number of recipes that included at least one spice, and highly inhibitory spices were greater in southern (hot) regions than in northern (cold) regions.

Prediction 5. *Quantities of spices called for in recipes should be sufficient to produce antimicrobial effects, and cooking should not destroy the potency of phytochemicals.* Despite the lack of data on the antimicrobial activity of spices in situ, the concentration of spices used in cooking are within the range (i.e., 30–2000 $\mu\text{g/ml}$) of the reported minimal concentrations of phytochemicals that were necessary to inhibit bacterial growth in vitro. In addition, most phytochemicals are

thermostable, although a few are destroyed by heat. The authors speculate that this could explain why spices like garlic, pepper, rosemary, and onion are added at the beginning of the cooking process, whereas others like parsley and cilantro are added near the end to prevent any loss in taste/effect.

Spices as Drugs

Many individual spices and blends have been used as medication to counteract a broad spectrum of conditions including impotence, dysentery, kidney stones, and high blood pressure. However, Sherman and Billing argue that the culinary use of spices differs from its medical use in three ways. On average, spices are included in very small quantities, to specific recipes, and are not correlated to the health status of the dinners. These differences would suggest that the targets of spice chemicals are on or in the food before it is consumed.

Alternative Hypothesis to Explain Spice Use

Sherman and Jennifer Billing also consider how well their spice use data fits into other, apparently proximate, explanations for this culinary practice. They concede that their finding that recipes from hotter places more frequently included spices, and more pungent spices, is consistent with the idea that spices are used to disguise the taste/smell of spoiled foods as food spoilage is faster and more frequent in hotter climates. However, they argue that this *disguise hypothesis* is flawed because it ignores the potentially strong negative effects, sometimes fatal, of ingesting contaminated food.

A second proximate alternative explanation inquired is that spicy foods are preferred in hot climates because they increase perspiration and help thermoregulation. The generality of this hypothesis, however, is limited since only a few spices, like chili, can cause sweating and does not contribute to explain the spice use in different temperatures. Furthermore, the human body

already has physiological mechanisms to regulate the organism temperature as needed.

Finally, Sherman and Billing consider three alternative ultimate explanations. The first is that spices, being difficult to obtain (expensive, rare, or both), could be used as honest signals of wealth and social status. A profligate use of spices would be possible only for wealthy or highly ranked individuals. Although this hypothesis could apply to rare spices with very restricted ranges, it does not explain the positive correlations between spice use and temperature and the patterns of use of common spices. In addition, Sherman and Billing draw attention to the fact the rarest spices tend to be used in the tropics, where they are endemic and often cheap. The second ultimate hypothesis is that spices supply chemicals that, in low concentration, have beneficial effects (e.g., micronutrients, antioxidants) other than inhibiting foodborne bacteria and fungi. The authors argue that the generality of this hypothesis, however, is also limited. Even if the phytochemicals found in spices like garlic, onions, and cloves can modulate metabolism and reduce free radicals, most spices do not have these properties. Moreover, it does not explain the positive correlations between spice use and temperature. Finally, Sherman and Billing consider the null ultimate hypothesis that spice use may not confer any benefits, other than enhancing food flavor. If this holds, they argue, spice use patterns should correspond to the local availability of spice plants. The relatively long history of spice trading and the extensive use of spices (e.g. pepper) in countries where they do not grow, however, suggest that the effect of local availability may be limited. The lack of correlation between the number of countries in which each spice plant grows (naturally or cultivated) and the number of countries in which it is used is presented as further evidence that the use of spices is not regulated by its local availability.

Origin of Spice Use

As an attempt to answer the question of how did spice use begin, Sherman and Billing hypothesized that people started using spices due to

their appealing flavors or possible digestive or vermicial effects. As a consequence families that created the habit of using spices would face food poisoning and suffer from foodborne illnesses less frequently than families that did not use spices, especially in hot climates. Additionally, spice-using families would have been able to store foods for longer, increasing their protection against energy shortages, a great advantage during periods of food scarcity. Observation and imitation of the culinary habits of these healthier families could have provided a fast way to disseminate spice use through societies.

Eventually, however, new microorganisms would immigrate, or local bacteria and fungi would evolve resistance to the local spices, and food would be potentially unsafe again. To solve this problem, and to circumvent newly learned food aversions, a different spice or set of spices could be added to the recipe. Over time, due to iteration of this process, the number of spices per recipe would increase, especially in climates favorable to microorganisms, where foods spoil rapidly. Consequently, spice synergism and variability could provide new antimicrobial benefits and improve the palatability of food again, helping to reinforce the conditioning between spicy dishes and safe foods.

Conclusion

Sherman and Billing collected evidence to support their hypothesis that humans seize the defensive compounds used by plants and put them to similar use in cooking, making food safer for consumption. Over time, our coevolutionary race with foodborne pathogens lead to a significant increase in the variety of spices used per recipe, particularly in hot places. In sum, the use of spices essentially contributes to the health, survival, and fitness of individuals and, hence, should be understood within an evolutionary perspective.

Definition

Darwinian medicine can be defined as the application of principles of evolutionary theory in medical research and clinical practice. It utilizes and synthesizes various theoretical models and research from a variety of disciplines, including psychology, psychiatry, physiology, genetics, behavioral and health sciences, and anthropology. Symptoms or impaired functioning might represent evolved responses or, contrariwise, the absence of successful adaptation to a certain environmental factor. Accordingly, putting illness, diseases, or pathophysiological mechanisms in the evolutionary perspective can be helpful to understand the origin and significance of the symptoms and may provide some indication to deciding whether to offer symptomatic relief or not.

Introduction

Medicine is based on human biology, and biology at any organizational level can only be fully understood in view of evolutionary processes. Theory of evolution and related model provide a unifying and integrating framework for all biological processes and functions. Correspondingly, the knowledge of evolutionary processes contributes to a more comprehensive understanding of human biology, health, and diseases (Williams and Nesse 1991). Medical education and practice focuses largely on *proximate* causes, that is, pathological processes or anatomical distortions causing a disease, to develop diagnostic procedures and to promote therapeutic advances. Considering the *ultimate* aspects, namely, the evolutionary mechanisms which formed biological processes affecting the risks of developing a disease or the protective functions to avoid an illness, can be a significant addition to current models and practices in medicine (Stearns et al. 2010). The evolutionary framework can provide a more profound understanding of health problems or resilience, because it requires to analyze the ecological factors affecting the individual. Examining the effects of physical and social environment and other factors (i.e., ecological context) in regard to illness or health is a significant contribution to a more comprehensive view of why individuals get sick (Nesse and Williams 2012). However, Darwinian models of medicine do not state that diseases are caused by evolutionary processes, rather that these mechanisms alter the risk of developing symptoms or disease. Moreover, it is plausible to assume that multiple evolutionary mechanisms influence individual risk of illness (Gluckman et al. 2016). Simultaneously operating selection processes create trade-offs in adaptive systems or traits, and as a consequence, there will be inevitable restrictions in adaptive functions. This can be considered as one source of human vulnerability to illness.

Basic Principles of Darwinian Medicine

Analyzing the ultimate causes of diseases requires another perspective and the utilization of explanations on another level. The fundamental principles of evolutionary mechanisms have to be applied in medical models to gain more insights and new ways to interpret or understand pathological mechanisms or to better understand health and illness.

Most importantly, it has to be recognized that selective mechanisms benefit characteristics, which enhance the *inclusive fitness* of the individual. Survival and reproduction are the key elements of fitness suggesting that evolutionary processes do not promote health or longevity directly (Williams and Nesse 1991). Living longer or healthier might be advantageous in a more indirect way: increased period of parental investment can secure that the offspring reach maturity and its reproductive period. In biological context, resources are limited and not available for every individual. Consequently, the most vital task faced by all individuals is to successfully utilize resources (e.g., energy, time, etc.) toward survival and reproduction. Characteristics determining these trade-offs are the central elements of the individual *life history strategy* (also called as life history traits). Life history (LH) traits specify the patterns associated with survival and reproduction of the individual: growth, development, mating behavior, parental investment, and aging (Kaplan and Gangestad 2005). There are two significant environmental factors with essential impact on life history trade-offs: *unpredictability and harshness* (Ellis et al. 2009). These environmental factors reflect the availability of resources, morbidity-mortality rates, and the predictability of change of environmental factors. Mortality and morbidity up to the reproductive age were shown to be more impactful on inclusive fitness than age-specific fertility (Jones 2009).

The second key principle of evolutionary medicine is to clarify that beyond some single gene effects, the evolution of humans (i.e., phylogeny) and the individual developmental path (i.e., ontogeny) do not cause illness directly.

Evolutionary processes affect health rather in shaping individual susceptibility to certain diseases in particular environments (Gluckman et al. 2011). For example, to be exposed to a virus does not necessarily result in an actual illness, which is principally caused by the virus compromising the immune defense. Former infections can stimulate the immune system to protect the individual against subsequent similar infections. This *immunization* process is therefore context-dependent, which highlights the importance of environmental circumstances in adaptation.

This is the third major basic element of evolutionary models in medicine: most of the human characteristics are adaptive responses to challenges our ancestors faced in evolutionary past. However, human environment changed significantly and rapidly; thus, we face evolutionary novel conditions. The speed and extent of these changes challenges evolved human capacities (biological, physical, and psychological) and enhances disease susceptibilities (Nesse and Williams 2012). In the majority of human evolutionary history, individuals lived in small groups and changed their residence periodically leading to a diversified diet. This lifestyle enabled humans to be exposed more briefly to lower density of pathogens compared to modern individuals, living a more settled lifestyle mostly in densely populated areas boosting the risk of illness (Stearns et al. 2010).

These core principles help to understand and utilize Darwinian models in medicine and can provide a more comprehensive understanding of health-illness-related mechanisms in humans. Nevertheless, another significant contribution of the evolutionary perspective to medical education and practice is to highlight possible patterns how adaptive traits may lead to a disease or incapacity (Nesse and Stearns 2008).

The Effect of Evolutionary Environments on Disease Risk

As pointed out earlier, both the physical and social environments changed rapidly through *cultural*

evolution. Basic biological processes determining our traits and capabilities were adapted to different environments from our actual conditions. These *evolutionary* novel *environments* possess challenges to the individual and exceed their evolved capacity to adapt (Gluckman et al. 2011, 2016). For example, animal husbandry and agriculture transformed human lifestyle making individuals live in a more settled way. The proximity of each other and the animals together with the relative immobility increased the intensity of pathogen loads and made humans to be more susceptible to diseases. Other technical innovations (e.g., development of canals, means of transportation) enable parasites or toxins to travel long distance and be distributed in populations, where natural immunization did not occur in regard of these pathogens (Williams and Nesse 1991).

Another example of evolutionary environmental effects on health are *life history traits*. As discussed above, these factors form traits and behavioral strategies in order to maximize inclusive fitness of the individual. Resource scarcity necessitates decisions about resource expenditure (i.e., trade-offs) between actual and future reproduction or between to support offspring and rather to produce another (Kaplan and Gangestad 2005). The peak of investment in development (e.g., maturation, physical capabilities) and health-related functioning (e.g., repair functions, cellular and molecular maintenance) is selected to be utilized during the reproductive period and will be reduced in later life. Prolonged life span implies a longer post-peak reproductive period and a higher risk for illness or dysfunctionality in older age. Reduced ability to overcome infections or trauma and regeneration together with the aggregated harming effect of stress and exposure to pathogens for a long time period can cause disease or dysfunctionality. Health problems in the middle and older ages (e.g., osteoporosis, atherosclerosis, arthritis, neurodegeneration, and cognitive decline) can be characterized with similar features suggesting that these are the inevitable consequences of longevity (Gluckman et al. 2011, 2016).

Adaptions with Disadvantages

Evolved defense processes protecting the body against certain infections or toxins may become inappropriate or excessive and become potentially harmful for the individual. Adaptive biological responses of the body (e.g., pain, fear, or fever) are suppressed or unrealized until activated by the presence of threatening stimuli (e.g., toxins, environmental cues, or viruses). These regulation mechanisms are advantageous in situations where the energetic costs of activation do not exceed their benefits (e.g., health protection). However, defense processes can be activated in situations where they are less beneficial or even unnecessary and became detrimental. For example, fever – one of the most frequent accompaniments of infections – can be considered as a significant antibacterial reaction activating immune responses, but highly elevated fever for an extended time period can increase morbidity (Nesse 2005; Stearns et al. 2010).

A second pathway how adaptations may become disadvantageous is the *coevolution* of humans with microbes. Our body includes several symbiotic relationships with bacteria, microbiota, in particular in the gastrointestinal tract. Recently, it is increasingly recognized in medicine that the examination and interpretation of these mutual relations is important to better understand human health. On the other hand, there are numerous adverse pathogenic organisms our microbiome fighting against in an evolutionary arms race. The consequences of the biological relationship with the microbial world are mainly formed by the rapid generation time of these organisms, leading to an accelerated evolution of these creatures compared to humans. Quicker development and shorter life span enable the production of multiple generations in a shorter time period, creating the opportunity for pathogens to outcompete human defense mechanisms. For example, the intensive use of antibiotics is suggested to trigger the selection of resistant strains, and at higher rates of antibiotic cures, these strains can spread at high frequency and increase the risk of illness (Nesse and Williams 2012).

Evolutionary “design” compromises can be considered as another pathway of adaptive processes with possible pathological accompaniments. For example, the well-known case of the appendix can suitably illustrate this phenomenon: this small blind part of the human digestion system has no function anymore, but it was important in the evolution of the primate clade. The exclusively vegetarian diet required a much extended gastrointestinal track to provide a longer digestion time and to enable the adequate extraction of essential nutrients from the food. Humans still have the appendix despite the fact that it is superfluous and potentially dangerous (an infection leads to appendicitis), because to be selected out, the appendix is needed to shrink, which inherently stimulates appendicitis (Nesse and Williams 2012).

Evolutionary Selection Mechanisms Creating Adversities

In accordance with life history traits, it is plausible to suggest that harmful mutations affecting the health during the reproductive period should be selected out of the population (Jones 2009). Nevertheless, some recessive forms of diseases can be found at an increased frequency within the population, which suggest the effect of *balancing selection*. Types of selective processes referring to balancing selection can be accounted for maintaining higher frequencies of different alleles in the gene pool of a population. The main reason for this is if the heterozygous genotype represents a fitness advantage compared to the homozygote form (Gluckman et al. 2011, 2016).

Sexual selection is suggested to be essential in the evolution of many human anatomical features and gender differences. *Sexual dimorphism* in human traits and characteristics is represented by the shorter life expectancy and higher mortality of men compared to women. These differences can be understood as a result of sexual competition and mate-seeking: successive competition for a mate implies greater fitness payoffs for men. Characteristics enhancing mating success

also influence health: for example, higher level of testosterone can be advantageous in competition with other men (due to the increased body mass and aggressive behavior) but has some deteriorative effects in suppressing immune responses, making the individual more prone to infections (Gluckman et al. 2011, 2016).

More recent human history has also health-related consequences: *assortative mating* (homogamy) can result in a magnified prevalence of mutations within a population, which can be considered rather infrequent in other communities. This mating pattern (a certain form of sexual selection) is driven by similarity: individuals with similar phenotypes (e.g., body size, skin pigmentation, or age) mate with one another with a higher probability than random and increases the rate of genetic relatedness within the family (Gluckman et al. 2011, 2016).

Conclusion

Models of Darwinian medicine allow a broader range of explanation and interpretation of disease-related risks and have therefore implications for medical interventions and public health. However, to improve the comprehension of these models, gene-environment interaction selection processes and combination of gene-environment interactions should be examined in detail. Evolutionary medicine has overlapping domains with other contemporary evolutionary studies. Accordingly, to the further development of this research agenda, the diverse domains have to be integrated, and a new synthesis of medical practice and ultimate mechanisms is needed.

Definition

Darwinian medicine is the application of evolutionary principles to health and disease. In many instances, natural selection favors adaptations that improve the survival of individuals. In other occasions, however, natural selection can favor adaptations that have a negative impact on the survival, health, and well-being of individuals.

Introduction

One of the most striking features of living organisms is that they appear to have been designed for a purpose. A natural explanation of this phenomenon eluded scholars for centuries until the mid-nineteenth century, when Charles Darwin provided a solution to the problem. By carefully comparing different populations, their ecology, and geographical distribution, Darwin discovered that the appearance of design in living organisms is the product of a process he called evolution by natural selection (Darwin 1859). Natural selection sorts out the genetic variants that exist in populations of living entities; it weeds out those variants that are detrimental to the fitness of organisms but retains those that are beneficial. Because parents pass their genetic information on to their offspring, the beneficial variants slowly increase in frequency (Frank 1998). After thousands of generations, adaptations will accumulate in the population and organisms will appear as if they have been designed (Dawkins 1976).

This relentless Darwinian evolutionary process produces organisms with an extraordinary capacity to exploit resources, which they use to construct body parts and develop behaviors that improve their chances of survival and reproduction. Thermal insulation, binocular vision, and bipedalism are just a few examples of adaptations that allow organisms to outcompete their rivals in the constant struggle for survival. In some cases, however, organisms hold characteristics that work against their best interests but serve the interests of others. Honeybees body plan includes stings that they deploy in suicide missions against predators to protect their colonies. Ground squirrels are

willing to risk their lives to alert their social partners of a threatening predator (Trivers 1985). From a Darwinian perspective, such self-harming traits and behaviors are difficult to explain. William D. Hamilton, in his theory of inclusive fitness, provided the solution to this puzzle. He discovered that costly traits that increase the reproductive success of social partners can nevertheless evolve when these partners are close relatives and therefore share copies of their genes (Hamilton 1964). Thus, a trait can be favored either by increasing the reproductive success of its bearer (i.e., direct or Darwinian fitness) or by increasing the reproductive success of its bearer's relatives (i.e., indirect fitness). These two additive fitness components constitute the *inclusive fitness* of an individual, which is the target of natural selection.

Evolutionary theory thus answers a fundamental question regarding the purpose of organismal design: Organisms are designed to maximize their inclusive fitness. This principle of adaptive evolution has important consequences for the understanding of human health and disease. Our bodies contain copies of genes that increased the inclusive fitness of our ancestors, even if these copies predispose us to disease, misery, and decrepitude (Stearns and Medzhitov 2016). In other words, traits and behaviors that improve our ability to survive and reproduce can also have a negative impact on our physical and mental health. Natural selection solves the problem of survival and reproduction, not the problem of disease, happiness, or well-being.

Much of an organism's fitness depends on its ability to survive. Organisms need to fight off diseases, defend themselves against enemies and predators, while at the same time, maintain homeostasis, somatic integrity, and delay body deterioration. Because organisms can only access a finite amount of energy, they are unable to maximize all these functions simultaneously (Stearns 1992). Investment in one function can compromise investment in another function, and reproduction often has a negative impact on survival. Pregnancy can leave mothers susceptible to diseases, and maternal death during childbirth is not uncommon. Larger body size has survival and

health benefits but sometimes investment in the immune system compromises growth and adult body size. These and other constraints on organismal design often leave us susceptible to disease and poor health.

Survival, Life History, and Kin Selection

Before exploring the main ideas surrounding the problem of survival in evolutionary biology and Darwinian Medicine, let us first analyze the core concepts of adaptive evolution, which can be more precisely defined using the language of mathematics.

In mathematical terms, fitness is the maximand of natural selection. That is, traits that increase fitness will spread throughout the population, while traits that reduce fitness will tend to vanish from the population. While differences in fitness cause adaptive evolutionary change, not all evolutionary change occurs because of variation in fitness, where evolutionary change is defined as change in gene frequency. An important case of nonadaptive evolutionary change occurs because of class-effects. Class-effects happen when individuals find themselves in different conditions, and they occur in a vast array of scenarios. For instance, some individuals are born in privilege while others in poverty; some individuals are born females while others are born males; and some individuals are young while others are old. These differences in individual quality (or condition) matter for the calculation of fitness, which captures differences in the genetic make up of individuals, rather than differences in their quality or condition. For instance, the genes of individuals that are born in privilege may increase in frequency because of their privileged condition, even if their genes are inferior to the genes of those born in poverty. Thus, a general mathematical formulation of fitness needs to take the condition of individuals into account.

Let $w_i \rightarrow_j$ be the contribution of a class- i individual to the class j . To make the argument clearer, let us consider, for instance, that class represents the age of each individual. Then, when an age- i individual survives, its contribution

to the age- $i + 1$ class will be $w_i \rightarrow i + 1$. When an age- i individual gives birth to offspring, then its contribution to the age-1 class will be $w_i \rightarrow 1$. In this particular case, “class” represents the age of an individual, but “class” can be any other feature of an organism and its surroundings, such as body weight or number of social partners. The general equation that describes the fitness of an individual, denoted by w , is then given by:

$$w = \sum_i^{\omega} u_i \left(\sum_{j=1}^{\omega} w_{i \rightarrow j} v_j \right) \quad (1)$$

where u_i is the frequency of class- i individuals in the population, ω is the maximum age of an individual, and v_j is the reproductive value of a class- j individual (Frank 1998). Reproductive value is an asymptotic measure of fitness and is defined as the contribution of an individual to the gene pool of future populations (Frank 1998).

It is worth considering the specific case when classes represent the age of individuals. Assuming a stationary population, Eq. (1) can be written as:

$$w = \sum_{i=1}^{\omega} l_i f_i \quad (2)$$

where f_i is the fecundity of an age- i individual and l_i is the probability that the individual survives to age- i . Equation (2) tells us that an organism can increase its fitness either by improving its fertility rate, i.e., f_i , or by improving its survival, i.e., l_i . Further, because organisms are less likely to be alive at older ages, selection will act less strongly at older ages. This has implications for the type of genes that evolve in populations. For instance, genes that improve reproductive performance at age 20 (i.e., higher f_{20}) may be favored by natural selection, even if these genes have a detrimental effect of similar magnitude at age 45 (i.e., lower f_{45}). This type of selection regime may underlie the evolutionary origin of many later-life diseases, including cancer and other noncommunicable diseases, as we shall see in more detail below.

The analysis of social behavior is usually done through the lenses of Hamilton’s rule (Hamilton 1964), which is the condition that determines whether a social trait will increase in frequency. Hamilton’s rule partitions fitness into a direct and

an indirect component. The direct component gives the effect of the behavior on the personal fitness of the actor, while the indirect component gives the effect of the behavior on the personal fitness of the actor’s social partners. Hamilton’s rule follows directly from Eq. (1) and in its simplest form is given by:

$$-c + br > 0, \quad (3)$$

where c is the fitness cost of the behavior to the actor; b is the fitness benefit enjoyed by the recipient; and r is the relatedness between the actor and the recipient. The behavior will evolve if the condition holds. Hamilton’s rule allows us to classify behaviors into four types, depending on the sign of the fitness costs and benefits, as follows: if $c > 0$ and $b > 0$, the behavior is said to be altruistic; if $c < 0$ and $b > 0$, the behavior is said to be cooperative; if $c < 0$ and $b < 0$, the behavior is said to be selfish; and if $c > 0$ and $b < 0$, the behavior is said to be spiteful. Relatedness plays a pivotal role in the evolution of social behavior because it determines the value of benefits. All else being equal, the higher the relatedness between the actor and the recipient, the higher the probability that altruism evolves. This has an impact on the environmental and social conditions that favor the survival of individuals, as we shall see below.

When studying survival problems, it is useful to consider a different formulation of Hamilton’s rule:

$$-v_A C + v_R B r > 0, \quad (4)$$

where C is the survival cost of the behavior to the actor; B is the survival benefit enjoyed by the recipient; and v_A (or v_R) is the reproductive value of the actor (or recipient). This formulation of Hamilton’s rule highlights the importance of reproductive value to the evolution of social behavior. Lower (or higher) values of an actor’s reproductive value favor altruistic (or harming) behaviors. Lower (or higher) values of a recipient’s reproductive value favor harming (or altruistic) behaviors towards the recipient. Reproductive value gives a measure of individual

quality, and this quantity is especially relevant to the understanding of survival-related behaviors (Rodrigues 2018).

Forms of Survival

Traits that improve our survival prospects come in different forms. Although we can classify traits in many different ways, it is useful to classify them according to whether they are more or less flexible (Stearns 1992). At one end of the spectrum, we have traits that are constitutively expressed. That is, they vary little with environmental conditions. They can be expressed throughout the entire life of an individual, but their expression can also be limited to a certain age range, and they may depend on a few genes. Other traits, called plastic traits, depend on the environment. The capacity to adjust traits as a function of the environment is denominated phenotypic plasticity. Structural body size, for instance, largely depends on the nutritional intake between infancy and late adolescence. A common pattern in nature is that poor nutrition leads to smaller adult body sizes while good nutrition leads to larger adult body sizes. Traits like structural body size are plastic but irreversible. Once the growth period of an organism ends, structural body size becomes a permanent characteristic of the individual. The process that gives rise to these traits is called developmental plasticity. Other traits, by contrast, are reversible, and therefore, they show more flexibility. They may be temporary responses to environmental factors or to the state of individuals. Sun tanning, for instance, occurs whenever an individual is exposed to sunlight but fades as soon as the external stimulus ceases. Finally, some traits, such as behavioral responses, can be even more flexible, and they allow individuals to quickly react to changes in their physical and social environment.

Below, we will describe some of the adaptations that improve human survival. We will start by considering traits that are constitutively expressed. We will then describe how phenotypic plasticity allows us to cope with the challenges of the environment. We will consider developmental

plasticity but also behavioral traits, where we will emphasize kin selection. Finally, we will describe how psychological traits and decision-making processes provide a first barrier against pathogens and other threats, and how they can mediate behavioral and physiological responses.

Constitutive Traits

Many of our survival adaptations are built-in. That is, they are constitutively expressed, and therefore, they depend little on the environment. In some cases, it is possible to identify the genes that underlie these traits and mutations that disrupt their normal expression can lead (or predispose us) to disease. In this section, we illustrate how constitutive traits influence human survival, their function, and their impact on fitness.

Resistance to malaria is one of the most well-studied constitutive human traits. Malaria is an infectious disease caused by the *Plasmodium* parasite, which is carried in the saliva of insects – the vector – and injected into the red blood cells of humans – the host. Because the *Plasmodium* parasite targets red blood cells, the genetic variants that confer resistance to malaria, such as sickle cell or thalassemia, usually affect the shape of these cells. These genetic variants are not widespread among the human population. Instead, they predominantly occur in sub-Saharan Africa. Evidence that these genetic variants are adaptations that evolved through the selective pressure of the *Plasmodium* parasite is diverse, and it includes population genetics and physiological studies as well as statistical analysis of demographic parameters.

First, detailed genome-wide analysis has found a strong correlation between the frequency of the variants and the geographical areas where malaria is endemic, with a negligible presence of the variants outside these areas (Jallow et al. 2009). Further, statistical analyses of these populations have revealed that the mortality rate of infants and children that carry the genetic variants is significantly lower than the mortality rate of those who do not carry the variants (Aidoo et al. 2002). Moreover, blood tests found a lower density of parasites in children with the genetic variants (Komba et al. 2009).

While these studies show that the genetic variants that confer resistance to malaria can provide multiple benefits, they are not widely spread among the human population for good reasons. The benefits of resistance carry significant costs. For instance, the sickle cell form of resistance to malaria modifies the shape of red blood cells, which increases the risk of anemia (Rees et al. 2010).

Constitutive traits have also allowed human populations to extend their diet range. This has enabled humans to move into new ecological niches or to improve their ability to survive and adapt to changes that persist in the environment. The recently acquired evolved capacity to drink milk after infancy illustrates this scenario. The domestication of cattle and other animals and the advent of dairy farming had a dramatic and lasting impact on the environment of human populations (Durham 1992). Domesticated animals could be used as working animals and as a source of meat but at the same time, they also made milk readily available to humans. Until the domestication of animals, milk was only part of the diet of infants and young children, and it depended on breastfeeding. After weaning, no other reliable source of milk was available, and humans would lose their ability to process milk. These conditions changed with the domestication of animals, after which milk became available across the entire lifespan of an individual. Genetic mutations that allow humans to digest milk beyond childhood, a phenomenon called lactase persistence, have since spread in the human population. The rate at which lactase persistence has increased in frequency since it first emerged in the human population suggests that this trait is under strong selective pressure (Tishkoff et al. 2007).

Constitutive traits also protect humans against infectious diseases. The human immunodeficiency virus (HIV) was one of the most devastating infectious diseases in the late twentieth century. Prior to the discovery of a new generation of drugs, HIV infection was in most cases a death sentence. For a vast majority of the population, the life expectancy after an HIV positive diagnosis was limited to a few years. In a few rare cases, however, individuals were shown to be resistant to

HIV. The virus utilizes receptors to bind to and infect white blood cells. Individuals that are resistant to the virus carry a mutation that inactivates these receptors (Heeney et al. 2006).

Genetic variants have also allowed humans to expand their geographic range. For a vast majority of human populations, living in high-altitude Tibet and Andes would be nearly impossible. At high altitude, oxygen density is extremely low, and therefore, without acclimatization, high altitude is often fatal to humans. These adverse conditions, however, have not prevented populations of Tibetans and Andeans to live at high altitude. Genetic and physiological analyses have shown that these populations have several adaptations that enable survival at such high altitudes. Physiological analyses, for instance, have shown that Andeans have a higher blood flow, a mechanism that allows them to survive at high altitude (Gluckman et al. 2016).

We have seen how genetic variants allow individuals to improve their odds of survival, either by becoming resistant to infectious diseases, by increasing their diet range, or by allowing them to explore new ecological niches and environments. These variants often come at a cost and therefore they may also predispose humans to diseases.

Phenotypic Plasticity

Let us now turn the attention to traits whose expression depend on the environment. We will first consider traits that become fixed after early-life development (i.e., irreversible traits), and we will then consider flexible (or reversible) traits, where we will focus on kin selection and social behavior.

Developmental Plasticity

Early-life environmental conditions can impact later-life survival and susceptibility to disease. One of the most well-known cases of this phenomenon has been extensively documented in analyses of the Dutch famine cohort (Lumey et al. 2007). Typically, when individuals share identical environmental conditions, they are expected to express similar phenotypes. Thus, it is intriguing when individuals sharing the same

environmental conditions exhibit significant amounts of phenotypic diversity. This was the puzzling observation that motivated many of the Dutch cohort studies (Lumey et al. 2007). First, scientists found that the Dutch population showed a significant amount of variation in the incidence of noncommunicable diseases, such as diabetes or obesity. Second, they found that this variation did not show any apparent correlation with their current environments. High incidence of noncommunicable diseases was eventually traced back to the early-life conditions of the affected individuals. Individuals that were in utero when their mothers fell victim to the Dutch famine because of the German siege were significantly more likely to develop noncommunicable diseases later in life (Roseboom et al. 2006). Why detrimental conditions during early-life development affect later-life susceptibility to disease remains a major question and the subject of much discussion. There are two main hypotheses for an evolutionary explanation of this phenomenon.

The first hypothesis requires the anticipation of later-life conditions (Gluckman et al. 2005). It assumes that individuals use their early-life environment to predict their later-life environment. Individuals can then anticipate their later-life environment and prepare for it in advance by developing phenotypes that are adaptive in the predicted environment. For instance, let us imagine that higher reproductive rate is adaptive in harsher environments. If individuals are born in harsh environments, then the hypothesis predicts that they should develop physiological aspects of their phenotypes that facilitate higher reproductive rates later in life. There is, however, a problem with this mechanism. If there is a mismatch between early- and later-life environments, then individuals will end up expressing a phenotype that is suboptimal in their later-life environment. Thus, this hypothesis requires a strong correlation between early- and later-life environments. In the context of health and disease, later-life ill health would then be explained as a phenotype-environment mismatch that contributes to high levels of susceptibility to noncommunicable diseases later in life.

The second hypothesis proposes that early-life environment constrains the phenotype of individuals (Monaghan 2008). More specifically, early-life hardships constrain the range of phenotypes that individuals can develop, the best of which are still subpar. Under such scenario, later-life diseases do not occur because of a mismatch between early- and later-life environments but because of developmental constraints. Individuals born in poor conditions are simply making the best of a bad job.

It is still unclear which of these two hypotheses best explain abnormal levels of noncommunicable diseases among the Dutch cohort, and the significance of predictive adaptive responses in general. Comparative studies in animals provide little evidence for adaptive predictive responses to early-life environments (Uller et al. 2013), and a statistical analysis of a pre-industrial Finish population found no support for adaptive predictive responses (Hayward et al. 2013).

Behavior and Kin Selection

While our own genes and phenotypes are crucial for our survival, in many occasions, we rely on others to survive. During infancy, we rely on parents: they provide physical protection, nourishment, a cozy environment, and they even contribute to the development of our immune system. Such devotion of parents towards their children evolves for very good reasons: there is a one in two chance that parental genes have a copy located in the genome of offspring. Transmission of genes between parents and offspring aligns their interests, and therefore, parents are willing to provide substantial amounts of care to their children (Hamilton 1964). However, when we explore the repercussions of this argument further, we encounter a darker side of human behavior. As individuals become less and less related, the incentives for cooperation subside, and incentives for aggression may even creep in. This gradient of behavior as a function of relatedness can be seen in multiple aspects of our social lives. Frequently, both the nuclear and extended family are composed of highly related individuals, and therefore, most of the times, youngsters experience

harmonious interactions with those around them. In some cases, however, the composition of families departs from this kin-based structure, and when unrelated individuals are present, violence is more likely to break out (Daly and Wilson 1988).

Detailed statistical analyses have shown that the presence of stepparents increases the risk of violence towards young children, with Data showing, for instance, that the mortality rate of infants is higher when a stepparent is present (Buss 2019). Alongside kinship, there are several other factors that play an important role in the social lives of youngsters. For instance, the age and marital status of mothers has been shown to have an impact on the mortality of infants and children. Infants born to single young mothers are more likely to perish (Daly and Wilson 1988). Two underlying factors may contribute to this outcome. First, younger mothers have a longer reproductive life ahead of them, and therefore, they will have plenty of opportunities to become mothers again, which means that they “value” their current offspring less than older mothers. Second, the absence of a partner may impose additional economic and social stresses that compromise the survival of the offspring.

Parents are the main caregivers of infants and offspring, but grandparents also fill an important role. Grandmaternal care of offspring is intrinsically connected to an almost unique human trait: menopause. Menopause makes human life history trajectories significantly different from those of our closest relatives, such as the bonobos and chimpanzees. Female chimpanzees, for instance, reproduce until old age and therefore do not experience menopause. This suggests that the family lives of humans have undergone important changes since we first diverged from our most recent common ancestor. The most common evolutionary explanation for menopause is based on the evolution of grandmaternal care (i.e., the grandmother hypothesis; Hawkes et al. 1998).

The evidence for the grandmother hypothesis is diverse. While the average inter-birth interval of chimpanzees is 5–6 years, in humans it is 3–4 years (Galdikas and Wood 1990). Shorter inter-birth intervals allow humans to have babies

at a higher rate, and grandmothers may have been instrumental for this transformation. Research has shown that grandmothers collect food items that children are unable to collect, and food gathered by grandmothers constitutes an important part of a child’s diet (Hawkes et al. 1997). Further, a review of the literature has shown that the presence of grandmothers reduces the mortality rate of infants (Sear and Mace 2008). These and other findings strongly suggest that reproductive senescence (i.e., menopause) in humans is an adaptive trait that is associated with the redirection of a grandmother’s resources towards their grandchildren.

Above we have seen how kin selection explains some of the variation in human behavior. High relatedness explains parental and grandparental care of infants, children, and adolescents. Low levels of relatedness explain neglect, aggression, violence, and crime. As a result, family and group composition have an important impact on the survival of all individuals, but especially on those that are most vulnerable, such as infants and children.

Psychology, Decision-Making, and Survival

So far, we have seen how constitutive traits, developmental plasticity, and behavior all influence the survival of individuals throughout the course of their lifespans. Although organisms would certainly not survive without these adaptations, in many instances, the first line of defense is encoded in the brain.

Psychological traits are the first line of defense against predators, toxins, pathogens, as well as other aspects of the environment that threaten the lives of individuals (Buss 2019). Negative emotions and feelings like fear, anxiety, or disgust help us avoid dangerous substances or situations. Anxiety may work as an alert system that signals the presence of predators or aggressive conspecifics. Disgust may caution us against potential sources of viruses and pathogens. Positive emotions and feelings such as happiness, hope, or excitement can also improve our own survival prospects as well as the survival of our friends and relatives. Feelings of courage and love towards daughters and sons fill the lives of many mothers and fathers and are crucial to enact the

behaviors that improve the survival of these offspring.

The evolutionary biology of psychological traits is difficult to test. However, a growing number of experimental studies have been able to provide important insights about the adaptive role of psychological traits. Disgust, in particular, has been the focus of much attention. It has been shown that sensitivity to disgust increases during pregnancy (Buss 2019). In a web-based survey, researchers found that disease-relevant images were rated as more disgusting than disease-irrelevant images. Further, they found that female disgust sensitivity was higher than male disgust sensitivity across all ages, and bodily fluids of relatives were reported to be less disgusting than those of strangers (Buss 2019). These findings lend some support to the idea that disgust is a psychological trait that is involved in the avoidance of sources of pathogens.

Decision-making plays a crucial role in our survival. Our decision-making system is composed of different subsystems, which include emotions, feelings, instincts, intuitions, memory, and reasoning. These processes and states occur both at the conscious and subconscious levels, and they interact with perception during decision-making. The cognitive system works in conjunction with the physiological system and physiology can override our cognitive system. For instance, under severe nutritional deprivation, our physiological system shuts down the ability to conceive (i.e., amenorrhea). When resources become available and food intake increases, the reproductive system is turned on again, and the cognitive system takes over the decision-making processes that affect childbearing.

Our decision-making and perceptual systems are the product of natural selection, and therefore, they are designed to further our fitness. As such, they are particularly sensitive to fitness costs, and they often seek to minimize large survival costs, even when this leads to a higher rate of decision-making errors or to perceptual errors. For instance, when people are located at the top of a height, individuals can overestimate vertical height by as much as 29% in relation to a scenario where they are located at the bottom of the

height (Buss 2019). The perceptual error makes sense from an evolutionary perspective. Underestimating such height could lead to large costs due to injury, and it could even lead to death. In general, our decision-making and perceptual system tend to exaggerate features of the environment that can impose large survival costs.

Our decision-making system is highly contextual, and small changes in the environment can have a large effect on our behavior. For instance, when asked to assess others, people take into account subtle features of our environment, such as ambient darkness. In a darker environment, people tend to emphasize negative stereotypes. In a well-lit environment, by contrast, people tend to disregard negative stereotypes (Schaller et al. 2003). Cooperation and reciprocity are also highly sensitive to environmental conditions, in general, and to social environment, in particular. In a public goods game, the presence of a pair of “watching eyes” increases the contributions of individuals to a public good (Bateson et al. 2006). Most of these decision-making processes occur at the subconscious level. When participants are deciding the value of their contribution to the common good, they are not consciously and explicitly thinking: “if there is a pair of watching eyes, then I will make a more substantial contribution to the public good.” Likewise, when people are rating others, they are not explicitly making the calculation: “if it is dark, then rate your neighbors more negatively.” Despite occurring at the subconscious level, these decision-making mechanisms probably have an adaptive basis. A pair of watching eyes may be a cue for policing, which is probably an ancestral mechanism to enforce cooperation in small hunter-gatherer groups. Further, it is naturally more difficult to ward off an attack in darker places, a factor that may trigger an alert mechanism, which in the particular case of the aforementioned study may assume the form of negative stereotyping.

We have seen how our psychology and decision-making system are designed to improve our survival, rather than to provide an accurate description of reality. This explains why we exaggerate some features of the environment (e.g., height), why we exaggerate the intent or

personality of other individuals (e.g., aggressiveness), and why we are prone to errors (e.g., improve survival, but increase error rates). We have also seen how our psychology and decision-making system are highly contextual, how little changes in the environment can lead to significant changes in behavior, and how multiple subconscious cognitive processes contribute to our decision-making. This has implications for evolutionary approaches to public health, as we shall see below.

Survival and Medicine

Identifying and understanding the adaptive function of traits is a core objective of evolutionary biology. This understanding can be extremely powerful when applied to health and disease. Diseases have multiple effects on human bodies, and therefore, they are often described and diagnosed by a suite of symptoms and signs. Typically, symptoms are the target of medical treatment, either because they are seen as undesirable effects of a disease or because they are identified as the cause of the disease. In some occasions, however, symptoms can be the body's evolutionary response to disease. Thus, the treatment of symptoms that are identified as "undesirable," when they are in fact body adaptations to fight off disease, can aggravate the state of the patient.

There are some case studies in which the targets of medical interventions have now been shown to be a body's response to fight disease. Lower levels of iron have been typically seen as a homeostasis problem, and therefore, the target of medical therapies with the aim of restoring the homeostatic levels of iron. Recent findings, however, should caution us against this view. For instance, the growth of some pathogens and parasites depends on iron. Without iron, pathogens' growth rate slows down or stops altogether. Thus, increasing the availability of iron in the bloodstream can actually lead to an increase in the growth rate of the pathogen and therefore aggravate the disease (Gluckman et al. 2016). Fever is another symptom that has typically been the focus

of medical therapy. However, fever may be a strategy to fight off disease. Certain pathogens show lower replication or survival rates when temperature is raised, even if this is just by a few degrees (Gluckman et al. 2016). Thus, mild fever can lead to faster recovery times. In sum, an evolutionary perspective on disease can alter medical practices and ultimately improve the health and survival outcomes of medical interventions.

Implications for Public Health

The integration of evolutionary biology and public health is still in its early stages, and therefore, some progress is still needed to develop a fully functional evolutionary approach to public health. This barrier between the two fields arises because they emphasize different dimensions of human lives. Evolutionary biology aims to uncover the ultimate causes of human behavior and how they evolved in our ancestral environment. These studies are based on the main principle of natural selection, which states that individuals are fitness-maximizing agents, and therefore, they do not rely on principles of rationality or agency. On the other hand, public health researchers seek to promote health-related behaviors in the context of modern environments. This research program emphasizes human rationality and agency as the main drivers of behavioral change, and it does so within the constraints of the current social and cultural context.

Bridging this gap will require further interdisciplinary studies. Directly importing knowledge from one field to the other does not work. For instance, our ancestors lived in a low-calorie environment, and therefore, obesity was virtually absent throughout human history. However, proposing such low-calorie ancestral environment as a public health intervention to curb the current levels of obesity is certainly not an option. On the other hand, public health interventions often seek to raise awareness about the long-term consequences of health-compromising behaviors, with the aim of promoting the benefits of healthier behaviors. These lifestyle changes in behavior often assume rationality. However, as we have

seen above, rationality can be at odds with the evolutionary drivers of the targeted behavior, which perhaps explains the low efficacy of theory-based public health interventions (e.g., Kinmonth et al. 2008). Applying evolutionary biology to public health interventions thus requires a detailed analysis of how adaptations evolved in our ancestral environment, but also how they play out within the context of current physical, social, and cultural environments.

It is clear that human-driven environmental, social, and cultural changes often have long-term and unforeseen consequences for public health. Piped water, sewerage, and other technologies have reduced infant, child, and overall mortality to unprecedented levels, which contributed to an increase in life expectancy. At the same time, the means of production and distribution over the past few centuries have improved substantially, which has led to a shift from a low- to a high-calorie environment. These transformations have had positive but also negative effects on human health. While they caused a rapid decrease in the incidence of communicable diseases, they also caused a dramatic rise in the prevalence of non-communicable diseases (Corbett et al. 2018). The introduction of contraception has increased the number of menses per lifetime, which in some Western populations is three times more than in natural-fertility populations. This may have contributed to an abnormal increase in the incidence of later-life cancers (Gluckman et al. 2016). These problems are difficult to understand with current approaches to public health, which are often short-sighted, focus on single populations, and do not consider the evolutionary history of traits and populations. Evolutionary biology puts these problems in a broader evolutionary and historical context. Comparative studies allow us to assess the ancestral form of traits and therefore understand why these traits cause ill health in modern environments. Contraception, obesogenic environments, and fewer sources of mortality create a mismatch between our ancestral and current environment that leads to exaggerated and unhealthy forms of traits, a factor that underlies novel epidemics and diseases. This evolutionary understanding of the historical development of

diseases can provide new insights and suggest novel approaches to public health interventions.

An important theoretical tool that can be used to guide public health interventions is life history theory (Stearns 1992). Life history theory can predict the impact of environmental changes on population-wide traits, including health-related traits. Because of its predictive power, life history can caution us against our own cognitive and cultural biases, which sometimes underlie the failure of public health interventions (Kahneman 2011). Cognitive biases, such as the reverse naturalistic fallacy, can skew public health interventions that, despite their virtuous goals, can end up having unfortunate consequences for public health. This can be illustrated with a recent development initiative in Ethiopia. The goal of the initiative was to reduce the energetic expenditure of mothers in rural Ethiopia in order to improve the overall well-being in the community. This, however, had unintended consequences for infant malnutrition, which is already one of the major health problems in Ethiopia as well as in many other African countries. Unfortunately, the development initiative may have aggravated this problem. A statistical analysis of the population after the intervention revealed an increase in birth rate (Gibson and Mace 2006). If more babies are born, then, all else being equal, each baby will be less well nourished. From the perspective of public health researchers and others, the outcome of the initiative may be puzzling. Why, in some instances, would mothers and families inadvertently adopt a behavior that could harm their offspring? From an evolutionary perspective, however, there are circumstances under which this outcome is expected. As we have seen above, the target of natural selection is individual fitness, not well-being. Maternal or paternal fitness is sometimes maximized when more babies are produced, even when this carries a cost to each individual baby. This evolutionary trade-off between offspring number and offspring quality may explain the unintended, and unfortunate, consequences of the intervention. These outcomes could be cautioned if interventions include an evolutionary assessment.

Lifestyle diseases represent some of the most important and debilitating diseases in Westernized societies. To same extent, these diseases depend on the decisions and behavior of individuals regarding their diet and other health-related factors. Thus, the success of many public health interventions depends on the capacity to promote behavioral changes in societies. It is now well understood that small changes in the environment can drive significant behavioral change. Work on behavioral economics, experimental psychology, nudge theory, and cognitive sciences have shown that human decision-making deviates significantly from the rationality assumption that characterizes many studies of human behavior. This work has shown that humans can heavily discount future costs, that human decision-making often relies on heuristics, and that perception is often context-dependent. It is also becoming clear that evolutionary theory can provide a unifying explanation for these findings. In particular, many of these cognitive biases can be understood as mechanisms designed to minimize current survival costs at a cost to error rates and future survival or reproduction. Thus, evolutionary theory can provide a systematic method for identifying aspects of the environment that can lead to effective behavioral changes in the context of public health interventions. For instance, public health interventions that focus on the long-term benefits of behavioral change are less likely to be successful than public health interventions that focus on short-term benefits.

An important evolutionary concept that should be taken into account in the design of public health interventions is the idea of mismatch. As we have seen above, behaviors depend on several decision-making systems, on our perception, and on mechanisms that are tailored to solve specific problems. This cognitive apparatus works remarkably well in modern environments, despite having evolved in our ancestral environment. In some cases, however, there is a mismatch between our evolved problem-solving mechanisms and modern environments. In our ancestral low-calorie environment, a taste for sugar and fat

were crucial to prevent death and ill health during periods of nutritional deprivation. In a modern high-calorie environment, however, this problem-solving mechanism contributes to the ongoing obesity and diabetes epidemic. In evolutionary parlance, there is a mismatch between our evolved decision-making mechanisms and our current environment.

Because our decision-making system is designed to improve survival, an understanding of specific problem-solving mechanisms can lead to novel public health interventions. Further, we can apply evolutionary models to understand the population-level and long-term impact of public health interventions. To illustrate these points, let us consider the scheduling of reproduction, which is a major evolutionary problem of medical significance, and includes some of the most important decisions faced by men and women during their lifetime. Both man and women need to decide when to have the first baby, how many they should have, and the interval between each baby. At first sight, this is an extremely complex problem, as many factors can potentially affect these decisions. From an evolutionary perspective, however, there are a few key parameters that should mediate these decisions. In particular, life history theory predicts that reproduction should depend on extrinsic mortality, infant mortality, the cost of each offspring, maternal age, resource availability, food insecurity, and on several other factors (Stearns 1992). Indeed, a worldwide statistical analysis has shown that life expectancy alone can predict as much as 68% of the variation in age at first birth (Low et al. 2008). This finding, among others, strongly suggests that mothers take local mortality into account during their decision-making process. Still unknown, however, are the specific mechanisms that are driving such decisions. It may well be that multiple environmental and social cues shape our perception of mortality, such as crime rate, the health status of neighbors, local news, and others. Nevertheless, identifying these mechanisms is a crucial step towards the design of novel

evolutionary-based public health interventions. Decreasing the indicators of mortality rates can lead to a delay in motherhood, an improvement in education, and to many health benefits that these behavioral changes entail, both for mothers, families, and offspring.

Evolutionary biology can also help us identify mechanisms of survival, and this can be used to inform public health interventions. For instance, one can co-opt the neural circuits that mediate grandparental care. As we have seen above, later-life survival is thought to have evolved because of grandparental care. Thus, mechanisms that are associated with grandparental care are likely to trigger the expression of mechanisms and processes that affect later-life survival. For instance, bringing children and elders together may stimulate the neural circuits involved in the survival of elders and thereby improve their health and longevity. Some evidence supports this hypothesis. A statistical analysis of a contemporary population (i.e., the longitudinal Berlin Aging Study) has shown that the mortality hazards of grandparents that provided childcare were 37% lower than those that did not (Hilbrand et al. 2017). One can also hijack the mechanisms involved in the evolution of cooperation and reciprocity, such as familiarity (de Waal et al. 2008). For instance, writing more personal letters seems to improve the response rate of individuals. This may be because personal letters activate the neural circuits associated with reciprocity and cooperation, and therefore, people may feel compelled to respond more to personal letters than to impersonal letters (Scott and Edwards 2006). This approach can be used to improve the response rates of medical surveys and screening programs.

Conclusion

Natural selection favors those traits that increase the fitness of individuals. Over evolutionary time, this process leads to the accumulation of adaptations in the population and the appearance of organismal design. To a large extent, the fitness

of organisms depends on their ability to survive, and therefore, many adaptations are geared towards this purpose. Organisms need to find food, protect themselves against enemies and predators, and fight off parasites and pathogens while maintaining body homeostasis and somatic integrity. These traits are often mediated by psychological traits and decision-making processes, which constitute the first line of defense against pathogens, predators and other sources of mortality. Survival, however, is not always aligned with fitness, the primary target of natural selection. In such cases, survival can be compromised, and this can predispose organisms to disease and ill health. An understanding of adaptive survival mechanisms to fight off diseases can improve medical interventions. Moreover, an understanding of evolved survival mechanisms can elucidate the behavioral responses of individuals to environmental changes, which can be used to improve the efficacy of public health interventions.

Definition

A wide variety of hypotheses about the function and evolution of mental disorders.

Introduction

The Dutch ethologist Niko Tinbergen (1963) famously argued that to understand why organisms behave as they do, one needs to ask four different kinds of question. Firstly, *causation* questions are about the physiological mechanisms involved in causing a particular behavior. Secondly, *development* questions relate to the role of the behavior in the organism's ontogeny. Thirdly, *function* questions are about the adaptive value of the behavior, that is, its contribution to the organism's survival and reproduction. Finally, *evolution* questions relate to our understanding of the behavior's phylogeny, that is, the history of its changes throughout evolutionary time. The first two kinds of question are often bundled as proximate questions, while the latter are called ultimate or evolutionary questions.

Tinbergen's taxonomy can also help us make sense of the wide variety of research questions and explanations in the history of psychiatry. Biological psychiatrists have always asked questions about the causation of dysfunctional behaviors and mental states, hoping to find

answers in our DNA, our brain, or our blood. Others have taken a rather developmental perspective, identifying the internal (e.g., regression) and external (e.g., trauma) factors involved in developing mental illness. Mutations, brain abnormalities, antibodies, and traumas are all examples of *proximate* causes of mental disorders.

It is much less known, however, that many psychiatrists have also engaged with *ultimate* questions about mental disorders. In fact psychiatrists have been asking such questions since evolutionary theories became known. In recent years, research about the function and evolution of these illnesses has been brought together as "evolutionary psychiatry" or "Darwinian psychiatry." This entry opens with a brief history of Darwinian psychiatry. It then critically discusses four of its explanatory models of mental illness. Finally, it considers Darwinian psychiatry's relevance for both psychiatric practice and psychiatric research.

A Brief History of Darwinian Psychiatry

In the past 150 years, many psychiatrists have been tempted to put evolutionary theories to use in their efforts to understand and explain various aspects of mental disorders. Most of the initial attempts were based on now-outmoded "evolutionisms," such as Lamarckism and degeneration theory. Later attempts drew upon developments in orthodox Darwinian theory, such as ethology and the modern synthesis. From the 1990s onward, the latter attempts are collectively referred to as "Darwinian psychiatry" (McGuire and Troisi 1998) or "evolutionary psychiatry" (Stevens and Price 1996), while the former have been labeled as "psychiatric Darwinism" (Adriaens and De Block 2010). This section discusses two examples of each of these two strands in the history of Darwinian psychiatry.

Some contemporary Darwinian psychiatrists have credited Sigmund Freud as one of the founding fathers or pioneers of their discipline (e.g., McGuire and Troisi 1998, vii). Freud was indeed indebted to all sorts of biological theories of the day. In his posthumously published *A*

Phylogenetic Fantasy (Freud 1987 [1915]), for example, he attempted to link up our ancestor's vicissitudes during and immediately after the last Ice Age with our present day vulnerability to a series of mental illnesses. In his view, today's phobias bring back our ancestors' overwhelming fear when confronted with the privations of the Ice Age. Critics, however, have greeted Freud's evolutionary hypotheses with jeers, exposing them as textbook examples of the pervasive influence of Lamarckism and recapitulationism (or Haeckel's so-called biogenetic law). Freud has indeed always held on to these theories, and, openly so, considering his belief in "use inheritance" and the "biogenetic law" as "an audacity that cannot be avoided" (Freud 1939, p. 100). In this sense, Freud's evolutionary work fits in with psychiatric Darwinism, rather than with Darwinian psychiatry.

At the end of the nineteenth and the beginning of the twentieth century, Freud certainly wasn't the only scientist to consider regression, both in ontogeny and in phylogeny, as a key theme to understand mental illness. Darwin himself also believed that mental illness constituted some kind of regression to more primitive stages of human evolution, with psychiatric patients closely resembling children, "savages," and human ancestors in being able to experience the purity of emotions. In *The Expression of the Emotions in Man and Animals* (1872, p. 245), he approvingly quoted the British psychiatrist Henry Maudsley, saying that mental disorders are "a faint echo from a far-distant past, testifying to a kinship which man has almost outgrown." Darwin also expressed the view that emotions were based on involuntary and habitual actions which may or may not be, or have been, useful to the organism. Remarkably, in *The Expression* he discussed this usefulness mainly in terms of a Lamarckian use inheritance, rather than in terms of natural selection. It would be fair to say, then, that Darwin himself, like Freud, was a psychiatric Darwinist, rather than a Darwinian psychiatrist.

By contrast, contemporary Darwinian psychiatry originates in a series of theoretical developments in early twentieth-century evolutionary theory, including ethology and the modern

synthesis. The latter was itself in fact a series of syntheses – of Darwin's theories with Mendelian genetics, and of the resulting population genetics with other biological disciplines, such as ecology – resulting in a solidification of evolutionary theory. One of the many innovations of the modern synthesis was Theodosius Dobzhansky's theory of balancing selection. In the 1930s he noted that natural selection often maintains different alleles at a specific locus in our DNA, despite the fact that some of them are deleterious, and he hypothesized that natural selection favors heterozygotic forms because they are better at surviving and reproducing than homozygotes.

In the 1950s, geneticists substantiated Dobzhansky's hypothesis by revealing a trade-off between sickle cell anemia and malaria resistance in people of African and Mediterranean descent. The elegant logic of this case soon proved to be very inspiring in the realm of psychiatry. In 1964, biologist Julian Huxley collaborated with Ernst Mayr and two psychiatrists to hypothesize that schizophrenia may well confer some hidden fitness advantages to the relatives of patients suffering from schizophrenia, thus explaining how this heritable and highly prevalent disorder managed to escape natural selection (Huxley et al. 1964). The bottom line of their case was indeed that schizophrenia should be considered as part of a trade-off, in which it is somehow connected with an important adaptive trait.

Another school in contemporary Darwinian psychiatry reaches back to comparative ethology and the work of Konrad Lorenz and Niko Tinbergen. One of its seminal papers also dates from the 1960s, when the young psychiatrist John Price claimed, along Freudian lines, that many of today's mental disorders were in fact adaptive mechanisms in the social environment of our ancestors, enabling them to cope with the exigencies of a strict social hierarchy (Price 1967). Depressive symptoms, for example, would be excesses of behaviors related to a fall in that hierarchy. Price argued his case with a series of observations about similarities between human depressive disorder and the behavior of low-ranking hamadryas baboons and long-tailed macaques. The work of John Bowlby and

Harry Harlow belongs to the same tradition of ethological psychiatry, inspiring a number of psychiatrists in the later decades of the twentieth century to try to understand mental illnesses by relating them to analogical behaviors in non-human animal species as diverse as birds, reptiles, marsupials, and monkeys.

Darwinian Psychiatry's Explanatory Models

The distinction between psychiatric Darwinism and Darwinian psychiatry relates not only to a difference in the nature and validity of the evolutionary theories underlying them, but also to a difference in focus, where psychiatric Darwinists, including Darwin himself, had very little interest in functional accounts of (the mental states underlying) mental disorders. It was only with the advent of the modern synthesis that evolutionary scientists started to wonder why natural selection seems unable to eliminate genes involved in the etiology of mental disorders, given that many of these disorders are harmful to an individual's fitness and given that they are much more common than Mendelian disorders. Unlike the latter, mental disorders have frequencies that cannot easily be explained by means of a concerted action between mutation and selection (Keller and Miller 2006).

So how should we explain the occurrence and persistence of common, harmful, and heritable mental disorders? In answering this question, many Darwinian psychiatrists have followed some kind of (explanatory) adaptationist logic, assuming that adaptation (or complex design) is what needs to be explained in biology because it is simply the most interesting aspect of the evolutionary process (Lewens 2009). However, there are many ways to be an adaptationist about mental disorders. This section discusses three common adaptationist explanatory models in contemporary Darwinian psychiatry, contrasting them with a fourth and decidedly non-adaptationist explanation (for a more comprehensive overview of the many types of explanatory models in Darwinian psychiatry, see Faucher 2012, or De Block and Adriaens 2011).

The most controversial adaptationist explanatory model in Darwinian psychiatry is that mental

disorders are not disorders or dysfunctions at all. Rather, they ought to be considered as adaptations that, like all adaptations, have been spread over the population by natural selection because they confer some reproductive advantage to their bearers. Such adaptationist hypotheses have been and are still being defended in the literature today, particularly in relation to depressive disorders. Edward Hagen (1999), for example, has hypothesized that women affected by postpartum depression may signal that they are suffering an important fitness cost, either because they lack paternal or social support or because their newborn baby is in bad health. In this view, postpartum depression would be a bargaining strategy, enabling women to negotiate greater levels of investment from others.

Other researchers have proposed similar hypotheses for other mood disorders. Forty years after his seminal paper, for example, John Price teamed up with other psychiatrists and continued to argue that typical depressive symptoms, such as a loss of appetite and excessive ruminating, may have been designed by natural selection to signal yielding in a fierce social competition that cannot be won (Price et al. 2007), or to reconsider unfeasible ambitions and investments (Watson and Andrews 2002). The gist of these adaptationist hypotheses is that depression is not a disorder but a useful psychological mechanism that allows us to cope with the inevitable adversities of life, much like fever allows us to fight bacterial infections, and coughing and sneezing help us to keep our airways clear (Nesse 2001).

The idea that some mental disorders may have some functional significance is perhaps as baffling as it is alluring. Surely the persistence of depressive disorders across cultures and time must tell us something about their adaptive value. On reflection, however, this first kind of adaptationist explanation in Darwinian psychiatry lacks cohesion. For one thing, the analogy between depression and bodily defenses, such as fever and sneezing, does not hold. Fever may well be adaptive because it meets evolutionary biology's basic criteria for an adaptation. (That said, fever need not always be adaptive, since treating fever with Advil generally doesn't harm patients.)

For example, fever's form (raising the body's temperature) fits its function (to fight pathogens), since at least some pathogens, such as bacteria, do not like it hot. Also, most of the times, fever is evoked in appropriate circumstances, i.e., when and only when pathogens invade the body. Depression clearly does not meet these criteria (for an extensive account of this argument, see Nettle 2004). Many people become clinically depressed for no good reason at all. Moreover, the symptoms of clinical depression often obstruct its supposed function, as they make others more hostile and rejecting, and limit important social problem-solving skills.

Interestingly, though, many of the proposed functions of depression (bargaining, time-out, social navigation, etc.) do fit its normal counterpart, i.e., low mood, suggesting that low mood, rather than depression, could indeed be an adaptation. In this view, depression would be a dysfunction of low mood, or "adaptive behaviour gone wild," as Stevens and Price (1996, p. 94) have put it. More generally, even though negative emotions can be considered as useful reactions to situations with a negative cost-benefit outcome, they also tend to be oversensitive and prone to go off the rails. To account for this oversensitivity, Nesse (2001) has compared negative emotions with smoke detectors – their reliability requires them to express a number of false alarms, especially when the cost of such false alarms is low compared to the potential harm they protect against.

A second and somewhat less controversial adaptationist explanation of mental disorders brings us to the heart of contemporary evolutionary psychology. Evolutionary psychologists claim that our ancestral environment, i.e., our environment of evolutionary adaptedness (or EEA), differs substantially from our modern cultural environment. As John Tooby and Leda Cosmides (1992) once put it: "Our modern skulls house a stone age mind." As a result, they argue that we are much better at solving the problems faced by our hunter-gatherer ancestors than the problems we encounter in our modern world. Some Darwinian psychiatrists consider this mismatch to be the hotbed of many of today's

mental disorders. Some of these disorders may well have been adaptive once, but somewhere in the tempestuous transition from the world of our ancestors to our contemporary environment, they have lost their functional significance. Such explanations are commonly known as mismatch explanations of mental disorders.

It has long been known that human anxieties often involve natural threats, such as snakes, spiders, and heights. According to some Darwinian psychiatrists, these threats were probably common on the savannahs in Pleistocene East Africa, but they certainly aren't the most dangerous things in our contemporary environment. Thus it is that we do not fear guns the way we fear snakes, even though guns pose a much greater threat to our fitness today than snakes do (Ohman and Mineka 2001). Mismatch explanations have also been given for substance abuse disorders and eating disorders. Modern manufacture has created an abundance of substances that were as rare as they were vital in the world of our ancestors and for which natural selection carefully crafted intense cravings. As Steven Pinker (1997, p. 524) once noted: "We enjoy strawberry cheesecake, but not because we evolved a taste for it. We evolved circuits that gave us trickles of enjoyment from the sweet taste of ripe fruit, the creamy mouthfeel of fats and oils from nuts and meat, and the coolness of fresh water. Cheesecake packs a sensual wallop unlike anything in the natural world because it is a brew of megadoses of agreeable stimuli which we concocted for the express purpose of pressing our pleasure buttons." It may well have been adaptive to binge on certain substances whenever they were available, but that adaptive strategy has inevitably turned against ourselves in times of plenty.

The trouble with many mismatch explanations is that they are based on dubious assumptions. One of these assumptions is that the incidence of mental disorders is higher in modern environments than it has been in the past. However, we simply don't know anything about the mental health statistics of our ancestors, and while it is true that some contemporary epidemiological reports indicate an epidemic-like surge in clinical depression, for example, critics have objected that

such growing numbers are more likely an artifact of contemporary psychiatry's promiscuous diagnostic practices (Horwitz and Wakefield 2007). Another assumption of many mismatch explanations is that our bodies and brains have not been able to keep up with the dazzling pace of cultural evolution. By contrast, gene-culture coevolutionary theorists argue that we are a cultural species and that our brains have evolved to adapt to ever-changing cultural environments. Such adaptability explains how we were able to colonize nearly all continents and to adapt ourselves to climatologic, social, and ecological circumstances dramatically different from those encountered in the African savanna (Richerson and Boyd 2005). A third and final assumption underlying some mismatch explanations is that many of the mental mechanisms implicated in mental disorders are modular. Darwinian psychiatrists believe that our fear-regulating mechanisms, for example, are highly selective, automatic, and encapsulated. They are automatic because they escape cortical control; encapsulated because they are immune from the influence of ongoing cognitive processes; and selective because they are preferentially triggered by certain classes of stimuli, i.e., evolutionarily relevant threats, including snakes and spiders. Yet critics have shown that such threats produce the same effects on attention as evolutionary nonrelevant threats, such as ropes, syringes, and pens. More generally, they believe our fear mechanisms to be much more flexible than contemporary Darwinian psychiatrists would have us believe (Faucher and Blanchette 2011).

A third series of adaptationist explanations of mental disorders can be labeled as by-product explanations or, using a famous Gouldian term, *spandrel* explanations. In architecture, a spandrel is a spherical surface created by the crossing of a number of round arches. In biology, the concept of a spandrel is used to refer to a necessary by-product of some or other adaptive characteristic of an organism. An example of a spandrel is the snail's umbilicus, i.e., the cone-shaped hollow space within the whorls of a coiled shell. An umbilicus has no evolutionary function – it simply arises whenever one creates a shell by coiling a

tube around an axis (Gould 1997, p. 10754). At a later stage, some spandrels are co-opted by natural selection to fulfill a particular function. In some snail species, for example, the umbilicus is used as a brooding chamber to protect their eggs. Given that mental disorders themselves are (or were) unlikely to be adaptive, as argued above, the question is whether it makes sense to consider mental disorders as nonadaptive spandrels.

In Gould's own view, such spandrels are invisible for natural selection, neither enhancing nor subverting the fitness of their carriers. Spandrels, or so he believed, cannot possibly be maladaptive, as they would soon be eliminated by natural selection, regardless of the importance of the primary adaptation with which they are connected. Curiously, Gould seems to be oblivious here, both to his own admonishments not to overestimate the powers of natural selection (to break the connection between a spandrel and its adaptation) and to the fact that there are a number of cases in biology where the value of the primary adaptation is such that it offsets the disadvantages of its spandrels or by-products. Such examples are often conceptualized as package deals or trade-offs and include the classic and above-discussed example of sickle cell anemia.

Following Huxley's original 1964 hypothesis, many contemporary Darwinian psychiatrists believe that the sickle cell scenario may also apply to the evolution of some mental disorders. Schizophrenia is a good case in point. As Stevens and Price (1996, p. 146) note: "In a sense, schizotypic genes are like the genes responsible for sickle-cell anaemia, which enhance the well-being of carriers by protecting them from malaria while impairing those with greater genetic loading by afflicting them with anaemia." But what possible advantages could schizophrenia be associated with? While Huxley focused on physiological and particularly immunological advantages, most Darwinian psychiatrists believe that schizophrenia owes its evolutionary persistence to a genetic association with a highly valuable and (typically human) cognitive trait, such as language or creativity. Horrobin (2001), for example, has suggested that minor mutations in the genetic code of the fat metabolism of our

early ancestors, and the associated exponential increase of their cerebral capacities, have heralded the beginning of an amazingly creative new species: us. Yet the very same mutations also made us vulnerable for schizophrenia. In a sense, schizophrenia is the price we pay for our very humanity.

By-product or spandrel explanations imply that mental disorders have never been adaptations, even though they do have some kind of evolutionary history, more particularly as sidekicks or spandrels of highly valuable traits. As noted before, spandrel explanations are rather popular in contemporary Darwinian psychiatry, and yet they are the object of much criticism, even from within the discipline. According to Matthew Keller and Geoffrey Miller (2006), for example, it is highly unlikely that the evolutionary persistence of mental disorders is due to their being part of a trade-off, and for various reasons. Interestingly, their critique draws in part on the work of Gould.

First of all, they claim that most adaptationist explanations of mental disorders, including trade-off explanations, smell of panglossianism: “Evolutionarily oriented mental health researchers, such as Darwinian psychiatrists and evolutionary psychologists, often go to torturous lengths to find hidden adaptive benefits that could explain the evolutionary persistence of profoundly harmful mental disorders such as schizophrenia or anorexia, but these accounts are often frustratingly implausible or hard to test” (Ibid., 386). When charging evolutionary scientists with panglossianism, Gould and Lewontin (1979) did not only criticize their overly optimistic (or empirical) adaptationist view of the powers of natural selection (Lewens 2009). They also criticized them for being lazy in testing the predictions that follow from their hypotheses. Anyone can easily come up with stories about the function of, say, male baldness or being homesick, but there is an important difference between just-so stories and real science. Even Dennett agrees with this point: “To the extent that adaptationists have been less than energetic in seeking further confirmation (or dreaded disconfirmation) of their stories, this

is certainly an excess that deserves criticism” (Dennett 1995, p. 245). Now it may be true that some spandrel explanations of mental disorders amount to nothing more than just-so stories, but this certainly isn’t true for all of them. Nettle and Clegg (2005), for example, established that those artists who score high on particular components of a mild form of schizophrenia, i.e., schizotypy, also display enhanced mating success. Thus they suggest that by fancying male schizotypic artists, women would ensure the evolutionary persistence of a minor variant of schizophrenia. By providing evidence of a link between creativity and psychopathology, Nettle and Clegg have shown that spandrel explanations need not necessarily be Panglossian.

Secondly, Keller and Miller acknowledge the existence of trade-offs in nature, such as sickle cell anemia, but they also argue that such trade-offs are very rare. Moreover, given natural selection’s vigor and given the sweeping reproductive disadvantages involved in mental disorders, Keller and Miller expect trade-offs to be highly provisional phenomena, awaiting a better solution: “[S]election would strongly favour genetic events that overcome the costs of producing homozygotes, such as unequal crossover events that position both S and s [in the case of sickle cell anaemia] on the same chromosomal arm, so they can be passed on together without disruption, or mutations that reduce the fitness costs of either homozygote” (Keller and Miller 2006, p. 395). Basically, the authors would agree with Gould’s argument that strongly maladaptive features will soon be eliminated by natural selection. However, this argument is a probability argument which, in a sense, begs the question about adaptationism: exactly how omnipotent and ubiquitous is natural selection, especially when it has to deal with highly integrated organisms? Assuming that sickle cell anemia and schizophrenia are intricately connected to adaptations of primary importance, how likely is it that selection will break the correlations involved and come up with a better alternative?

Keller and Miller’s criticism brings us to their own attempt to make sense of mental disorders, which is part of a fourth and final series of

evolutionary explanatory models of mental disorders. In Darwinian psychiatry, these explanations are known as breakdown explanations or medical explanations, and they are explicitly non-adaptationist. As Dominic Murphy notes, for example, adaptationist explanations seem to assume that “none of our psychopathology involves something going wrong with our minds,” even though “nobody should deny that our evolved nature suffers from a variety of malfunctions and other pathologies” (Murphy 2005, p. 746). It may well be, for example, that low mood has some functional significance, but low mood, like any other trait or capacity, can also *dysfunction*, thus resulting in “malignant” sadness or clinical depression. From the perspective of breakdown explanations, it may well be useful to look for ultimate causes in explaining *normal* mental states, but mental *disorders* are proper dysfunctions caused by proximate causes.

Examples of such proximate causes are lesions and infections but also mutations. Keller and Miller’s explanatory model is based on the observation that the human genome is indeed particularly vulnerable to genetic mutations, i.e., tiny errors in our DNA’s xeroxing. These errors are the main source of genotypic variation. Most harmful mutations quickly disappear from the gene pool, but the bulk of genetic mutations have so little effect on reproductive success that they easily hold out during a number of successive generations. Thus the average human being is provided by his parents with five hundred up to two thousand slightly harmful mutations, half of which affect the construction and maintenance of the brain. Like many other traits, mutation load is continuously distributed across the population, so some individuals probably carry a few thousand brain-related genetic mutations, while others only carry a dozen. And the general principle seems to be that the more mutations one carries, the higher the chance of deviant behavior: “Individuals with an especially high load in mutations that disrupt a particular configuration of brain systems will tend to act in aberrant, harmful ways that provoke social comment and psychiatric categorization” (Keller and Miller 2006, p. 404). On this view, mental disorders are not veiled adaptations.

Rather, they are genuinely harmful dysfunctions, stemming from the immense mutational target size of the human brain.

Darwinian Psychiatry in Psychiatric Practice and Research

The evolutionary explanatory models discussed in the previous section go some way toward resolving the evolutionary paradox of common, harmful, and heritable mental disorders. In doing so, they may perhaps add to the solidification of contemporary *evolutionary theory*, but one wonders about their added value for contemporary *psychiatry*. What does psychiatry gain from its courtship with evolutionary theory? Traditionally, psychiatry has always been a hybrid discipline, dividing its time between research and practice, so our question can be further specified: what does Darwinian psychiatry have to offer to psychiatric patients and psychiatric researchers? This section discusses three examples of the discipline’s relevance for these target groups.

Many contemporary Darwinian psychiatrists are practicing psychiatrists, and their theoretical background indeed filters through to their therapeutic views and interventions. Firstly, Darwinian psychiatry can be instrumental in emphasizing that not all kinds of mental suffering are symptoms of an underlying dysfunction. Suffering may be as inevitable as it is useful. Anxiety and low mood, for example, are helpful defense mechanisms, enabling us to react efficiently and appropriately to adverse life events, such as losses and impending dangers. Extreme reactions to extreme events can still be normal. Secondly and relatedly, Darwinian psychiatrists can help change mere negative and stigmatizing views of mental illness, for example, in highlighting its connection to highly valued traits, such as creativity. Finally, some Darwinian psychiatrists, and especially ethological psychiatrists, have advocated more intense observation of patients in their social environment, arguing that suffering never takes place in a vacuum: “Psychiatric evaluation and treatment take place in offices and hospitals, rarely in patients’ natural environments, and the constraints that such practices introduce into diagnostic and treatment efforts are significant.

There is a not-so-subtle arrogance in the view that one can accurately understand patients' social environments simply by discussing these environments within the confines of one's office" (McGuire and Troisi 1998, p. 278).

However, Darwinian psychiatry's main contribution to contemporary psychiatry lies in its implications for psychiatric research. From the very beginning, Darwinian psychiatrists had high hopes of breathing new life into psychiatric research, particularly by bringing unification, sophistication, and solidification.

Firstly, Darwinian psychiatry promised to make an end to the incessant theoretical splintering of psychiatry (McGuire and Troisi 1998). Plagued by decades of trench warfare between competing theoretical frameworks, including psychoanalysis, biological psychiatry, phenomenology, and behaviorism, contemporary psychiatrists tried and tested two basic solutions, though without much success. One solution consisted in promoting the so-called biopsychosocial model. The model prescribes that all three levels – the biological, the psychological, and the social – must be taken into account when explaining mental disorders and treating patients, but it gives no guidance about how to prioritize choices, and so in practice it often devolves into eclecticism (Ghaemi 2010). Another solution consisted in giving up on theory altogether. Since 1980, contemporary psychiatry's ubiquitous *Diagnostic and Statistical Manual of Mental Disorders* (DSM) has steered an explicitly atheoretical course, hoping to bring unity to the field by focusing solely on clinical phenomenology, i.e., manifest symptoms. The problem with this solution is that the unity it generates is rather shallow and that it leaves unanswered the question how to connect the DSM's phenomenology with scientific research on the etiology of mental illness.

Darwinian psychiatrists believe that their discipline can provide a more successful solution to the problem of theoretical fragmentation in psychiatric research. As they point out, evolutionary theory has a track record in bringing together various domains in biology, including embryology, morphology, paleontology, and behavioral ecology. It did so by providing a theory about the interplay between on the one hand traits and

the genes involved in constructing them, and their environments on the other. Traits can only become (mal)adaptive in a particular environment at a particular time. The adaptive value of anxiety, for example, is always relative to the intensity of the adverse life event it relates to. Darwinian psychiatry could bring unity to contemporary psychiatry by overseeing the process of constructing both proximate and ultimate explanations of mental disorders.

Secondly, Darwinian psychiatrists can help refine contemporary psychiatry's methods and results. Thus they contend that good evolutionary explanations can provide the heuristic means to refine proximate explanations. Randolph Nesse and Matthew Keller's work on low mood is a case in point. In their attempts to demonstrate that low mood can be adaptive, they were able to confirm their prediction that different adverse life events correlate with different patterns of low mood features (Keller and Nesse 2006), even though they couldn't demonstrate that different feature patterns increase fitness in different adverse situations. Such research can help substantiate the search for more fine-grained mental disorder categories, the urgency of which is directly proportional to the mounting evidence against traditional disorder categories.

Thirdly, Darwinian psychiatry or, more broadly, evolutionary thinking in mental health care can help solidify contemporary psychiatry by contributing to the definition of its general concept of disorder. One of the most pressing problems of contemporary psychiatry is indeed its lack of consensus about how to define the concept of mental disorder. Jerome Wakefield attempted to tackle this issue by providing a hybrid evolutionary account of the concept in question. He argued that all and only mental disorders are harmful dysfunctions (Wakefield 1992). A mental mechanism is dysfunctional when it fails to fulfill the function for which it has been selected (by natural selection) in the past. A dysfunctional mental mechanism becomes a mental disorder when (and only when) it is experienced as harmful, either by the patient or by his or her environment. Depression is a mental disorder because it is both harmful and

dysfunctional, as it involves an evolved mental mechanism, i.e., low mood, that does no longer fulfill its function (whatever that is).

Wakefield's definition has been hailed by many psychiatrists as an important contribution to the field, but it brings its own problems. Wakefield claims, for example, that the function of a mechanism is related to its evolutionary history, rather than its contribution to the overall functioning of an organism. The problem with this view is that it is often impossible to find out the evolutionary function of a mental mechanism. Lacking such knowledge, we are thrown back on our own intuitions about the function of mechanisms – intuitions that often reflect our own petty values and prejudices (Faucher 2012). Wakefield (1992, p. 386) himself acknowledged the deadlock: "Because of the complexity of the inferences involved in judgments of dysfunction and our relative ignorance about the evolution of mental functioning, it is easy to arrive at differing judgments about mental dysfunction even on the basis of the same data."

Conclusion

There is ample evidence in the foregoing that Darwinian psychiatry is in fact a house of many mansions. Its advocates draw on a variety of traditions both in psychiatry, ranging from psychoanalysis to its sworn enemy, namely, biological psychiatry, and in biology, ranging from population genetics to ethology. Also, and testifying to the imaginative power of Darwinian psychiatrists, there is certainly no lack of hypotheses purporting to explain the occurrence and persistence of mental illness. Many Darwinian psychiatrists are adaptationists, arguing either that mental disorders are in fact adaptations, or that they are somehow genetically connected to an adaptation, or that they used to be adaptive. Some Darwinian psychiatrists also allow for non-adaptationist explanations, arguing that mental disorders are, and have always been, maladaptive. Some of these hypotheses have been tried and tested; others are little more than just-so stories. Given this heterogeneity, to hail

this wonderful discipline as the final turnabout in mental health care would be as presumptuous as to dismiss it altogether.

Definition

To be actively pursuing a romantic relationship with another individual.

Introduction

Courtship has been documented in many species (Moore 2002) and is commonly referred to as dating in humans and leads to mateship in all cultures (Greer and Buss 1994). Adolescence is the time period in which humans become increasingly interested in forming romantic relationships (Connolly et al. 1999). In fact, most North American adolescents have had at least one romantic relationship by late adolescence (Carver et al. 2003). By the 12th grade, boys spend approximately 5 h each week with girls, and girls spend an average of 10 h each week with boys, with each sex spending between 5 and 8 additional hours each week thinking about or talking with same-sex friends about the opposite sex when they are not together (Furman 2002). Connolly et al. (1999) found evidence for a series of transitions in adolescent social groups, changing from same-sex peer groups to mixed-sex peer groups, then to dating as part of the peer group, and finally leading to a dyadic romantic relationship that exists independently of the peer group. In college-age individuals, the romantic relationship is the most supportive relationship for men and one of the most supportive relationships for women (Furman 2002). Culture has an influence on the transitions between adolescent dating stages (Ha et al. 2010; Connolly et al. 2004). It has been hypothesized that romantic relationships in adolescence contribute to the development of an identity, the development of close friendships and family relationships, the development of sexuality, and the educational achievement and career planning (Furman and Shaffer 2003). Courtship rituals and behaviors are common in most cultures, and although the rituals vary between cultures, the ultimate goal of mateship stays consistent (Werner et al. 1992). These rituals may also serve as protective factors in the progression toward serious relationships, a concept investigated by Halpern-Meekin and Tach (2013),

mentioned in further detail in section “[Courtship Rituals and their Importance in Relationship Development](#)”. In order for courtship to occur, individuals must be able to signal interest in a potential suitor, and men and women have developed tactics to nonverbally communicate interest through body language (Grammer 1990) and can gain important insight to an individual’s potential as a mate using kissing as a cue (Hughes et al. 2007; Wlodarski and Dunbar 2014). A common modern approach to dating is through the use of online dating platforms. With access to a plethora of potential mates, individuals can use online dating websites and mobile apps to find a mate in a way that coincides with a busy schedule (Hobbs et al. 2017). Although online dating creates an easy way to meet new people, it is not without risks. People engage in a variety of forms of deception in an online dating context, many of which will be discussed in the following sections. The topic of dating and courtship will be discussed in detail in the following areas of research: (1) adolescents’ transition into dating, (2) courtship rituals and their importance in relationship development, and (3) the modern world of online dating.

Adolescents’ Transition into Dating

Adolescence is a time of many changes, including the transition into dating. It is understood that young adolescents understand the dynamics of romantic dating (Connolly et al. 1999) and it is a central topic of discussion (Simon et al. 1992), even if they have little personal experience. Through the years of adolescence, individuals become increasingly invested in romantic relationships, and much of adolescents’ social world becomes engrossed in romance and potential romantic relationships (Furman 2002). One accessible way for these young teenagers to learn about the world of romance is the portrayal of romance through various forms of media (Connolly et al. 1999). Perhaps one of the most influential sources of knowledge concerning romance comes from the development of mixed-sex peer groups (Connolly et al. 2000). Connolly et al. (2000) explain that through these mixed-sex groups,

individuals can meet potential romantic partners and have the opportunity to watch interactions between their peers. Adolescent romantic relationships do not reflect adult romantic relationships immediately; rather they go through a series of transitions to become familiar with the world of dating (Connolly et al. 2004). Stage models of adolescent dating propose two levels of romantic activities that take place before the dyadic romantic relationship stage. The first stage is the development of mixed-sex peer groups, followed by some peers forming pairs in the group and date while still participating in the group activities (affiliative dating), and the final stage is the formation of the dyadic romantic pair independent of the peer group (Connolly et al. 2004). While these stages exist, it is believed that adolescents do not follow a strict pattern of development and adolescents become interested in forming romantic relationships at their own pace (Furman 2002). Connolly et al. (2004) suggest development through the aforementioned stages of dating exists because social groups are of utmost importance in adolescence. Early romantic stages that encourage being a part of the mixed-sex social group and forming romantic pairs that function as part of the group will be favored by adolescents instead of immediately forming a dyad that functions independently of the group because this will draw an individual away from his or her social group. To further confirm the notion that social and romantic activities coexist in early adolescence, Connolly et al. (2004) examined the romantic activities and interest of young adolescents. They found that mixed-sex affiliative dating increased romantic interest in the young adolescents and led to romantic relationships. Further, their results supported a fluid model of romantic development that supports the stage model theory but explains that romantic development and interest do not replace mixed-sex peer groups and social activities, instead romantic interest and dating coexist with social groups and the activities the group partakes in (Connolly et al. 2004). In a study conducted to examine whether young adolescents have the same conceptions as adults regarding romantic relationships, Connolly et al. (1999) found

adolescents understand the core differences between friendships and relationships. The adolescents, aged 11–14, characterized opposite-sex friendships in terms of affiliation and relationships in terms of passion (Connolly et al. 1999). Adults, on the other hand, include emotional closeness in friendship and relationships, as well as commitment in relationships. Connolly and researchers speculate this could be because the age group in the study may be too young to conceptualize commitment and emotional closeness, as these are not yet important factors in their relationships with peers or romantic partners (1999). As adolescents mature, their opinions shift toward an idea similar to adults of what a romantic relationship is. Their findings also suggest there are cultural differences in the discussions regarding romance that takes place in friend groups, such that norms and expectations of romantic relationships vary depending on the cultural definitions of romantic relationships and how they should develop (Connolly et al. 1999). Even though early adolescent romantic relationships are based primarily on affiliation, older adolescents form relationships similar to adults, begin to seek out a partner to support their social and emotional needs, and turn to a romantic partner for support (Furman 2002). Furman (2002) states that this is due to maturation and continuous experiences as adolescents learn.

While adolescents can learn from the media and from peers about the nature of romantic relationships, teenagers can use their relationships with family members and same-sex peers to develop expectations for romantic relationships (Furman 2002). A study conducted in the Netherlands looked at indigenous and ethnic Dutch adolescents' romantic development and highlights the influence of parental and best friends relationships on romantic relationships (Ha et al. 2010). Ha et al. (2010) found that ethnic Dutch teenagers showed more commitment in romantic relationships when their relationship with parents was poorer, and they showed more passion in their romantic relationships when their relationships with their best friends were poorer. The researchers speculate these ethnic adolescents could be compensating for their poor-quality

friendships and parental relationships by investing more into their romantic relationships (Ha et al. 2010). They also explain that since the ethnic Dutch teenagers have cultural backgrounds from Turkey and Morocco where Islamic traditions are practiced, the collectivistic culture is dominant and influences parental decisions regarding their children's dating habits (Oyserman et al. 2002). Collectivistic cultures put emphasis on family and romantic relationships and rely heavily on interconnectedness and interdependence with one's family (Oyserman et al. 2002). To elaborate, ethnic parents tend to set more limits for their children in terms of who they date and set strict rules for dating which in turn can create tension between an adolescent and his or her parents (Ha et al. 2010). On the other hand, indigenous Dutch families follow a more individualistic culture (Oppenheimer 2004), and so these adolescents have the freedom to choose their partners based on their own standards, and parents let their children have the freedom to make their own decisions (Dion and Dion 1993). Ha et al. (2010) showed this could explain the lack of compensatory behavior toward romantic relationship partners of the indigenous Dutch teenagers. This study emphasizes the importance of familial relationships and the impact they have on adolescents' developing romantic interests and relationships.

Similar to the study conducted by Ha et al. (2010), Furman and Shomaker (2008) examined adolescents' romantic relationships relative to their relationships with close friends and their mothers. The researchers found that the affect of adolescents was more positive with their peers and romantic partners than with their mothers, even though their mothers had more positive affect than romantic partners. Further, the teenagers perceived more support in their romantic relationships than with their friends and mothers (Furman and Shomaker 2008). Furman and Shomaker (2008) speculate that adolescents try to avoid negative encounters with their friends and romantic partners because these relationships are more egalitarian compared to typical authoritarian parental relationships. Connolly et al. (2004) found a pattern similar to Ha et al. (2010)

regarding differential romantic activity based on cultural differences. Asian-Canadian adolescents engaged in less romantic activities, were less interested in romantic relationships, and had more same-sex friendships than the other groups of adolescents in the study, suggesting a cultural influence over romantic activity (Connolly et al. 2004).

Courtship Rituals and Their Importance in Relationship Development

Courtship can involve many different rituals and can encompass many different behaviors. Some of the more common examples of initiating a courtship or relationship are (1) the partners are chosen by family members without input from the couple, (2) the family makes the choice but the couple can decline, (3) the couple can select each other but the family can decline, and (4) the couple can decide whom they wish to date and the family has little say in the matter (Stone 1977). In some cases of courtship, there is very little courtship at all: in arranged marriages, there is no courtship; instead there are negotiations between the families of the individuals involved regarding prices and trades (Werner et al. 1992). In cultures where the couple and their families are both involved in the decision of marriage, gifts are exchanged, bride prices and dowries are discussed, and exchanges are made between families. These negotiations typically involve feasts and celebrations and gifts of money, jewelry, land, or animals, which are used to signal wealth. Further, in cultures where couples decide on their relationship, gifts are given to the couple, and little is exchanged between their families. Couples who have the freedom to decide whom they wish to marry do not usually involve their family until the relationship is more serious and there is a stronger commitment, and courtship usually takes place in public areas until the relationship is serious enough to involve family members. In terms of wedding ceremonies, western cultures adopt the tradition of the bride and groom coming together and meeting at a wedding ceremony, which signals they are equals entering into their

relationship. Other cultures have a different approach to marriage, with the groom, accompanied by his friends and family, picking the bride up at her family's house and bringing her to the ceremony: this is symbolic of the bride leaving her family and joining his (Werner et al. 1992).

In instances where couples must mutually agree on whom they wish to enter a relationship with, there are behaviors individuals can use to signal interest to another individual. For example, laughter has been defined as a courtship signal (Moore 1985) and is used to signal sexual interest in another individual (Duncan and Fiske 1977). Grammer (1990) conducted a study on laughter and body language and the messages they can portray. Grammer (1990) found that women use laughter as a tool more often than men do, and women use nonverbal cues more often than men. Specifically when interested, a woman will open her body up by extending her arms to seem engaged and look away from a man to highlight her profile from the side and accentuate her neck and breasts (Grammer 1990). This is consistent with male mate preferences, such that men prefer women who are young and fertile, as large breasts and smooth skin signal good health and fertility in women (Buss 1989). When men are interested in a woman, they will turn their bodies toward her and sit or stand with an open posture to imply he is intent and interested in her (Grammer 1990). This is consistent with female mate preferences for a man who is committed to her (Buss 1989). Interestingly, Grammer (1990) reported that women used their signalling postures only when a male was looking at her, and when he was looking away, she was watching him with her head tilted toward him with her arms and legs crossed, even if she was interested in him. While laughing, women use head tossing, an averted gaze, a protruded chest, and hair flipping to communicate interest in a male, and men tilt their heads and lean in while laughing to communicate interest in a female (Grammer 1990). Once interest has been signalled, one must decide if a certain individual is suitable enough to potentially begin a relationship with. Kissing is an important milestone in the courtship process, and Hughes et al. (2007) looked at romantic kissing as a sign of a good

partner. Females consider chemical cues like breath and taste, and the look of one's teeth when considering kissing someone, since these can cue health quality (Durham et al. 1993). Females reported a male being less attractive and less desirable if he was a bad kisser, and women are less likely to have sex with someone without kissing them first. This finding suggests women use kissing as a mate assessment tool (Hughes et al. 2007). This is in line with mate preferences in women, such that they look for mates with cues to good health and signs of commitment (Buss 1989). On the other hand, men prefer wetter kisses with more tongue, which could act as a signal for sexual receptivity (Hughes et al. 2007). When men were told a woman was a good kisser, they were more likely to rate her as attractive and more willing to date, engage in casual sex, and enter a long-term relationship with her (Wlodarski and Dunbar 2014). The effect of a woman being good kisser on a man's willingness to enter a long-term relationship with her from the study conducted by Wlodarski and Dunbar (2014) is consistent with findings from the study by Hughes et al. (2007) such that men and women think kissing a long-term partner creates greater emotional closeness and creates a stronger bond after sex when compared to a short-term partner.

Sex is important for courtship, and men and women have strategies in order to increase the likelihood of sexual encounters. A study conducted by Greer and Buss (1994) analyzed some tactics used by men and women to determine which tactics were used most often by men and women and which were most effective. Some of the strategies women use most often include directly requesting sex, increase sexual contact, indicate sexual attractiveness of their target, go to a private area, and dress and act seductively. A selection of the most commonly used tactics by men include verbal desire for sexual contact, directly requesting sex, imply commitment, increase attention toward their target, and imply sexual attractiveness of their target. In terms of which strategy proved most effective, men rated a woman directly asking for sex as most effective, and women rated a man telling her he loved her, was committed to her, and cared about her deeply

as most effective (Greer and Buss 1994). These tactics are consistent with mating preferences, such that men prefer a short-term mating strategy when possible (Buss and Barnes 1986), so perhaps women directly asking for sex is most appealing to men. Men's strategies are also consistent with women's mate preferences, as they prefer a long-term mating strategy and will choose a mate who is committed to her and will be emotionally supportive toward her (Buss and Barnes 1986). Women are more likely to dress seductively and enhance their physical attractiveness (Greer and Buss 1994), consistent with male mate preferences for a physically attractive mate (Buss 1989). Men use more tactics than women to increase the likelihood of sexual encounters (Greer and Buss 1994), consistent with the notion that women are the choosy sex in relation to mating (Buss 1989). When it comes to facilitating sex, men and women rely on tactics that exploit mate preferences. Other important milestones in the courtship process include giving one's partner a key to his or her apartment, moving in together, and engagement (Stanley et al. 2010). Couples who "slide" into these important milestones might experience greater relationship turmoil and poor relationship outcomes because these courtship milestones play a key role in relationship development (Vennum and Fincham 2011). Stanley et al. (2010) state that rituals like engagement are important in relationship development and may act as protective factors in a relationship because of how clear, mutual, and public the information is and that couples have a shared understanding of their relationship status. If these clear milestones act as protective factors, perhaps discordance between couples' reports of relationship progression indicates they "slid" into a more serious relationship instead of mutually deciding on meeting the next milestone, Halpern-Meekin and Tach (2013) postulated. They conducted a study to examine couples' reports of their relationship progression to see if discordance in reports was linked to marital quality. Halpern-Meekin and Tach (2013) determined discordance in relationship progression was linked with lower marital quality, and it is an indicator of "sliding" rather than mutually

deciding to progress in a relationship. This study shows that courtship rituals are important and also that mutual decisions from both partners are important for a healthy relationship.

The Modern World of Online Dating

Online dating has become an increasingly popular approach to searching for a mate. Bauman (2003) argues that romance and the courtship process have become a form of entertainment due to computer dating, since people will always have access to the mating market. Mobile dating apps are different from online dating websites in the experiences available due to the ability to take these apps wherever you take your smartphone (Hobbs et al. 2017). Many people enjoy using mobile dating apps because of how easy it is to use in a modern, busy schedule, and individuals now have access to many new potential suitors they may not have had access to before these mobile dating apps existed. Interestingly, Hobbs and colleagues conducted a study (2017) in which participants were asked how they would prefer to meet a partner, and over half stated they would choose meeting a potential romantic partner the traditional face-to-face way, and just under half of the participants said they would prefer to find a sexual partner the traditional way. Further, participants reported feeling embarrassed to tell someone if they had met a romantic or sexual partner online (Hobbs et al. 2017). Interestingly, Rosen et al. (2008) found people who prefer traditional dating have differing views on which characteristics are most important in a potential date from those who prefer online dating. People who prefer face-to-face dating value personal information, personality, and education to be most important factors in a potential mate, whereas people who prefer online dating stress the importance of communication style and physical attractiveness in a date (Rosen et al. 2008). The researchers speculate this could be because traditional daters have the opportunity to assess physical appearance immediately and must learn about an individual's personality and preferences as the courtship progresses. On the other hand, online daters can get to know a

person's personality and preferences from their profile or through email exchanges but must wait until meeting in person to assess physical appearance, since profile photographs can be deceiving (Rosen et al. 2008). Further investigation by Botnen et al. (2018) into the individuals who use mobile dating apps found that the use of these apps is associated with an unrestricted sociosexual orientation (looking for a casual sex partner rather than a long-term romantic partner) (Buss and Schmitt 1993). Specifically, an unrestricted sociosexual orientation explained the effects of looking for a casual sex partner and being comfortable picking up strangers (Botnen et al. 2018), which is consistent with the short-term mating strategy typically adopted by individuals who have an unrestricted sociosexual orientation (Buss and Schmitt 1993). Some individuals use mobile dating apps for casual hookups only (Hobbs et al. 2017), with findings that men use mobile dating apps for sex rather than a relationship and women use the app for to feel good about themselves because the attention makes them feel confident (Botnen et al. 2018). Hobbs et al. (2017) found similar results for mobile dating apps like Tinder, such that matching with someone works to boost one's self esteem because the apps are based on photographs of individuals. Hallam et al. (2018) found similar results in their study looking sociosexual orientation (preference for long-term or short-term mating) and online dating strategies. Hallam and colleagues concluded that individuals with an unrestricted sociosexual orientation prefer to use online dating for casual sex only, and individuals who adopt a restricted sociosexual orientation (preference for a committed, long-term partner) prefer to use online dating to look for a long-term partner and are motivated by romantic interest (2018). A study conducted by Blackhart et al. (2014) examined other factors that influence the individuals who use online dating sites. The researchers determined people who were highly sensitive to rejection were more likely to use online dating sites, perhaps because they could avoid rejection more easily through the Internet than it would be to avoid rejection in person. They speculate these individuals can more easily change aspects of their personality online and

can therefore feel more comfortable when interacting with potential romantic partners. These individuals who scored high in rejection sensitivity were also less likely to tell friends and family about meeting an individual online to avoid judgment (Blackhart et al. 2014). Hallam et al. (2018) found age influences the preference for mobile dating apps or online dating websites. Specifically, older individuals prefer to use websites, whereas younger people prefer to use mobile dating apps. They speculate this could be influenced by the preference for newer technology in younger adults, as younger adults are more open to new technology compared to older adults (Hallam et al. 2018). Individuals who engage in self-monitoring (altering one's personality based on reactions from one's audience) intentionally lie to prospective dates about their personality and interests so they appear to be more similar to their prospective date than they are (Rowatt et al. 1998). These self-monitoring individuals believe it is acceptable to alter aspects of themselves to increase interest from a potential partner, and there is a potential link of the tendency to self-monitor to high scores of neuroticism. The researchers believe the insecurity and anxiety experienced by individuals high in neuroticism may lead them to alter their personalities to impress a potential partner and to avoid rejection. Further, individuals who use self-monitoring techniques tended to alter characteristics related to personal preferences, attitudes toward love, and their own attractiveness, which can be considered trivial and are typically used to initiate interest in another person so courtship can continue. For example, if an individual alters small details about him- or herself to create similarities with a prospective date, it is seen as slightly more acceptable than lying to a long-term partner or lying to harm another individual (Rowatt et al. 1998).

While online dating does increase the dating market (Hobbs et al. 2017), there is an increased risk for danger and deception regarding potentially important details because there is no initial face-to-face interaction. Couch et al. (2012) conducted a study regarding potential dangers of meeting an individual online. These participants recalled the deception they encountered and

expressed their concerns. Participants recalled the most common lies they received were about relationship status, the intentions toward individuals they were talking to, and inaccurate profile photos. Many participants experienced exploitation of their emotional vulnerability, being lied to about others' intentions for the courtship, and the level of commitment the individual was interested in pursuing. Some participants recalled violence they had experienced from someone they had originally met online: a woman had her drink spiked for not sleeping with the man she met online, and another woman was stalked by someone she had recently began chatting with (Couch et al. 2012). Blackhart et al. (2014) expand on this by looking at personality factors and concluded people who score high in conscientiousness are less likely to meet in private with someone they met online, possibly due to their increased levels of caution. In the study conducted by Couch and associates, most individuals were concerned about people who were untrustworthy or dangerous, including prostitutes, scammers, and people from overseas, and a selection of participants recalled interacting with someone asking for money or to pay for a passport/travel visa (Couch et al. 2012). Aside from the attempt to receive money, it is puzzling why individuals decide to lie online, especially when research has shown that the first face-to-face meeting between individuals who originally met online does not fare well when an individual has been lied to (Sharabi and Caughlin 2019). Specifically, individuals who had been lied to experience a decrease in social and physical attraction, and have low expectations for future dates with this person, and also feel this person has low expectations too. Sharabi and Caughlin (2019) explain that when there is deception early in the formation of a relationship, it may cause individual to expect disappointment in the relationship and hinder potential progression toward a strong relationship. Research done by Ellison et al. (2011) revealed that some discrepancies are tolerable in an online dating context. Specifically, discrepancies in characteristics that are easy to change in the near future, like a hairstyle, were deemed acceptable, whereas characteristics that could not easily be

changed in the near future, like height or age, were not acceptable. The magnitude of the lie also affected the acceptability of a lie, such that smaller differences between what is presented and the truth are okay, but large differences are not. For example, lying about your age by 1 year is acceptable, but a difference of 8 years is not (Ellison et al. 2011).

A common area of deception in online dating involves physical attractiveness (Toma and Hancock 2010), and many people report that they are not completely honest online (Drouin et al. 2016). Since attractiveness is important to many individuals in a romantic context, it is common for less attractive individuals to attempt to enhance their physical appearance by selecting photos to share that increase their physical attractiveness (Toma and Hancock 2010). Toma and Hancock (2010) also report that women enhance their photos more often than men, consistent with the notion that men value physical attractiveness more than women (Buss 1989). Consistent with mate preferences (Buss 1989), men and women who were considered to be more physically attractive both received more emails from prospective dates, as well as women who had a lower body mass index (BMI) which is valued, and men with higher incomes (Hitsch et al. 2005), since a low BMI is valued by men and a high income is valued by women when considering potential suitors (Buss 1989). Another common area of deception involves self-presentation, defined as the alteration of one's personality or appearance to increase attractiveness in a certain situation or environment (Toma and Hancock 2010). It is common for individuals to exaggerate aspects of themselves to increase their attractiveness to a potential partner (Guadagno et al. 2012). Consistent with this notion, men change their personality characteristics and physical appearance when they wanted to meet an individual in person. Men exaggerated their agreeableness when communicating with potential dates over email and lowered their neuroticism to give the impression they would be a more emotionally stable partner than what may be true (Guadagno et al. 2012). Guadagno et al. (2012) explain this is consistent with the notion that females tend to be more

selective when choosing a mate (Buss 1989), so men would be more willing to change their characteristics to look more appealing.

Conclusion

Dating and courtship become a central aspect of humans' social lives beginning in adolescence (Connolly et al. 1999). As adolescents mature and learn about the concepts of dating, courtship rituals become important for signalling interest to another individual to determine if they reciprocate interest (Grammer 1990). Courtship rituals seem to be imperative in the development of a strong relationship because of the seriousness and clarity these rituals demonstrate (Halpern-Meekin and Tach 2013). Online dating platforms have increased in quantity and popularity over recent years, and the use of these platforms ranges from looking for casual sex partners to seeking a long-term romantic partner. The risk of these online dating platforms is that there is a lack of initial face-to-face interaction, leaving room for people to alter characteristics about themselves, like physical appearance or their intentions for seeking a partner. The dating world has evolved over the past decades and will undoubtedly continue to evolve over the coming decades, so it is important to continue to research this socially relevant topic of dating for new theories regarding dating and courtship processes.

Definition

Daughter guarding highlights the tendency of parents to monitor and control their daughter's mating behaviors in order to protect reproductive success.

Introduction

Ancestral perspectives regarding sexual traits and behaviors have evolved and serve as a function that has persisted throughout time. From an evolutionary perspective, mate selection and reproduction is a way to carry on fitness advantage (the ability to survive generation to generation) (Voland 1998). Today, parents often attempt to influence their children's mating behaviors through various methods and strategies, such as parental monitoring. Reproduction compromises a female's survival in regard to the physiological risks associated with pregnancy. As such, parental investment in their offspring's reproduction protects the offspring's sexual fitness. Evolutionarily, in hunter-gatherer populations, parents needed to ensure that their daughters were selecting mates that had the ability to support them, such as being proficient at hunting. Because of the physical costs associated with pregnancies, parents did not want offspring to be produced with mates that lacked the ability to secure resources. The purpose of ensuring reproductive success is to maintain positive genetic variation in a population and protect against the extinction of future generations (Voland 1998).

In modern day, daughter guarding through messages such as limiting sexual activity "when ready" and "not too early" serves to ensure the best mate for their daughter and further propel the passing of genes. Parental investment has existed throughout time and is exhibited through sexual selection. From an evolutionary perspective, behaviors exist because they serve a purpose in survival. Thus, daughter guarding behaviors strive to ensure the survival of the fittest.

Sexual Selection Theory

Sexual selection theory attempts to explain what factors drive mate selection. Various researchers have argued which factors comprise the establishment of this theory. This theory distinguishes between three main factors: female choice, male-male competition, and parental choice (Apostolou 2014). Within hunter-gatherer cultures, male-male competition was a means to compete for female access, attention, and reproduction, leading to the increased likelihood of ultimately being selected by the female. Both female choice and male-male competition coincide to ensure reproductive success. Although all factors are arguably important, parental choice best supports the daughter guarding hypothesis (Apostolou 2014).

Daughter Guarding Hypothesis

The daughter guarding hypothesis describes the phenomenon of parental investment in monitoring and/or controlling their daughter's mating behaviors in order to facilitate reproductive success (Perilloux et al. 2008; Kuhle et al. 2015). Through this lens, the daughter guarding hypothesis describes the adaptations parents possess that function to defend their daughter's sexual reputation, prevent unwanted pregnancy, preserve her long-term mate value, and protect her from sexual victimization (Perilloux et al. 2008; Kuhle et al. 2015). Parents developed the personal responsibility to protect them their daughters from sexual victimization because in the past, there was no law enforcement to prevent it.

Historically, in order to preserve lineage, consensual sex was seen as genetically beneficial; however, if the preservation of future generations was placed in jeopardy, males chose the action of force (i.e., rape) in order to increase generational survival and reproduction. For women, rape comes with a burden to bear in relation to future partner choice, harm to status, and the risk for unwanted pregnancy (Gottschall and Gottschall 2003). Damage to a daughter's mate value may prevent her from obtaining a high-quality mate

who can support her. This may result in economic and/or social strains on the parents (Perilloux et al. 2008). Because males (e.g., sons) do not bear children, parents are less restrictive regarding their son's sexual encounters (Perilloux et al. 2008).

Current Implications

Parents are more likely to control offspring behavior if parent-daughter opinions differ, thus creating a cycle of conflict specific to daughters. This cycle may lead to daughter guarding and monitoring of behaviors (Bovet et al. 2018). Furthermore, there is a causal relationship between parental monitoring and daughter sensitivity. The phenomenon of daughter sensitivity has occurred as females, in comparison to males, have evolved to be more sensitive to their parents' approval and opinions regarding future mates. Women experience parental monitoring at higher rates, and this direct relationship implies that women who were more sensitive toward parental opinion were also highly monitored. For instance, women report allotting greater emphasis than men on their parents' wishes (Dubbs et al. 2012). This relates to parental acceptance as well as the significance placed on parental approval (Apostolou 2009). Moreover, parental investment was also believed to be of significance in a potential partner, as females would report experiencing hurt feelings if their parents did not approve of their partner and would even contemplate "cutting off" the relationship (Dubbs et al. 2012).

Research indicates that parents are more likely to control their daughters' mating decisions than their sons and parents reported dissatisfaction over their daughter's sexual activity (Perilloux et al. 2008). Both parents and their daughters described mechanisms by which daughter guarding is implemented in their daily life, including control over behavior, approval of behavior, emotional upset over sexual activity, approval of mate choice, control over curfew, and control over clothing (Perilloux et al. 2008). Parents are less likely to allow their daughters to engage in

romantic relationships (compared to sons) in order to decrease the opportunity of sexual contact and to reduce the chance of sexual victimization. With these two objectives in mind, parents may object to their daughters engaging in physical intimacy at higher rates than their sons (Perilloux et al. 2008). Parents of sexually active daughters may feel compelled to monitor her sexual activity with more vigilance in order to protect her sexual reputation and mate value. Approaches parents utilize to monitor their daughter's behavior include enforced curfews to limit sexual contact, decreased time away from parental observation, and restricted choice of clothing to be less provocative (midriff tops, low cleavage, etc.) (Perilloux et al. 2008).

Within a developmental context, parents typically facilitate sex conversations with their children with the intended purpose to possibly encourage abstinence, highlight being selective with regard to whom they allow sexual access, to possibly delay sexual contact until she reaches older age, and to deter from a potential partner's sexual advances. These reasons are established in conversations with daughters rather than sons. On the other hand, sons are more likely than daughters to receive messages that sex should be fun (Kuhle et al. 2015). Parents also suggest to daughters that they should not partake in or mimic sexual activities illustrated in media.

Thus, daughter guarding is a strategy parents use to socialize their daughters to foster reproductive success and preserve mate value (Kuhle et al. 2015).

Conclusion

Daughter guarding may have been a significant evolutionary force in order to withstand reproductive pressures. Throughout history, daughter guarding has attempted to protect from untimely pregnancies in regard to physiological reproductive costs, including rape and sexual victimization. At present, daughter guarding behaviors continue to exist and are exhibited in influencing not only offspring's mate selection but also the

conversations parents have regarding sex with their offspring. Across cultures, parents may implement robust control over the mating decisions of their offspring. Daughter guarding has also served its purpose in defending a daughter's sexual reputation and value in the long term.

[Author; Philosopher](#)

Definition

David Benatar is a philosopher known for his writings about ethics, particularly involving procreation. He is considered one of the foremost authorities and proponents of anti-natalism.

Introduction

David Benatar is a South African philosopher, professor, and chair of philosophy at the University of Cape Town. He is the author of *Better Never to Have Been: The Harm of Coming into Existence* (2006), a treatise on anti-natalism, and *The Second Sexism: Discrimination Against Men and Boys* (2012), which chronicles wrongful discrimination against men, in the interest of advancing gender equality. While he is perhaps best known as a proponent of anti-natalism, he is also noted for writing about ethics, including topics in sexual ethics, male circumcision, female genital

mutilation, fetal pain, euthanasia, humor, and affirmative action. An opponent of speciesism, he has strongly advocated the ethical treatment of all sentient beings, including refraining from consuming animal products.

Anti-Natalism

Professor Benatar has gained prominence for his advocacy of anti-natalism, which opposes procreation. He has argued that coming into existence is always harmful, and thus it is immoral to bring new life into existence. This argument stems from the discrepancy between pain and pleasure, such that the presence of pain is always undesirable and the presence of pleasure is always desirable. In contrast, whereas the absence of pain is considered positive, the absence of pleasure is not necessarily a negative state and is better characterized as neutral. Missing out on pain by not being born is not equal to missing out on the pleasures of living. According to Benatar (2006), this basic asymmetry produces other asymmetries. For instance, bringing into existence, a child who will suffer can be considered regrettable, yet failing to bring into existence, a child who would lead a happy life produces no regret because of the lack of a person to lament it, or to be lamented. Since there is no person associated with not being born, no person exists to wish that they would be born to experience pleasures in life, because being is necessary for mental states such as a desire to be born. Further, even if a potential being might live a subjectively “good” life, it may not, and that risk outweighs the benefits of that life because the alternative – failing to be brought into existence – causes the nonexistent no harm while avoiding inevitable suffering in life.

Apart from the asymmetries of pain and pleasure, humans have a tendency to exaggerate the quality of their lives, underestimating past pain and suffering and overestimating pleasure and happiness. Such retrospective biases have empirical evaluation and support, such as the tendency of older adults to more readily recall pleasant memories and give more positive evaluations of autobiographical information (e.g., positivity

effect; Mather and Carstensen 2005). Although Pollyannaism (Matlin and Stang 1978) is psychologically powerful in retrospection, it does not change the fact that human lives are filled with suffering moment to moment. Thus, Benatar has surmised that procreation should be avoided because new life is new pain, as it is certain that every new person will suffer to some degree. Since there is no moral imperative to reproduce, humans have no reason to procreate new suffering. Acknowledging how deeply reproduction is entrenched in human evolved psychology, Benatar does not set the expectation that people stop reproducing immediately. He has set forth a plan for a “phased extinction” (Benatar 2006), with the goal to reach the ideal human population of zero, because it is the only way to ensure zero suffering. Phased extinction calls for the species to wean off reproduction across several generations, allowing the death rate to exceed the birth rate until humanity ceases to exist. He has favored this “dying off” plan to being “killed off” because of the potential suffering that could be brought about by killing already living humans en masse. To fill individual psychological drives for parenthood in the meantime – the primary practical impediment to his plan – Benatar has suggested adoption as a viable option. This might not be a perfect alternative to genetic offspring, however, given the evidence indicating that children tend to suffer greater domestic abuse and neglect from genetically dissimilar stepparents than from genetically related parents (e.g., Daly and Wilson 1980). However, Benatar has pointed out that humans have similarly evolved gratification delays which render the species uniquely capable of selecting its own extinction. Furthermore, humans are capable of culling their reproduction as modern contraceptive techniques have made pregnancy all but completely avoidable.

It is important to note that Professor Benatar has drawn a distinction between coming into existence and continuing existence. Although it is preferable not to have existed, once a person has been brought into existence, that person has a justifiable interest in continuing to exist and minimizing the suffering in his own life and those around him. In other words, “life may be

sufficiently bad that it is better not to come into existence, but not so bad that it is better to cease existing” (Benatar 2006, p. 212). Anti-natalism has often been misinterpreted as advocating suicide, and indeed, Professor Benatar (2006) has acknowledged that in some circumstances, taking one’s own life is a reasonable response, yet it need not follow the acceptance of anti-natalism. He has been careful to recognize that the costs of continuing to live must be high enough to outweigh the cost of taking one’s own life, including the impact on others. He has thus set the threshold for beginning new lives much higher than the threshold for continuing lives in progress, because those in existence have an interest in continuing to exist, where in contrast, no such interest in coming into existence is present in the nonexistent.

Although he has advocated anti-natalism on philanthropic grounds – that it is better for the potential new person not to be brought into existence – Professor Benatar has also presented an argument against procreating on misanthropic grounds. He has suggested that humans should not reproduce because of the tremendous harm that the species causes other sentient beings, both human and nonhuman (Benatar 2015). This premise portrays humans as both victims and perpetrators of tremendous harm in the world. As such, humans should not only refrain from creating new victims of suffering but also new causes of suffering. For both philanthropic and misanthropic reasons, Benatar has proposed that sexual intercourse is most ethical when it is non-procreative. He has thus bypassed the ethical debates surrounding many reproductive technologies, instead indicating that women are morally obligated to avoid impregnation and, when necessary, to terminate pregnancies as soon as possible, preferably before the fetus can feel pain (at about 27–28 weeks of gestation; Benatar and Benatar 2001). He has thus put the onus on defending procreation, and not abortion, taking a pro-death position (Benatar 2006). Because anti-natalism contradicts psychological drives that have promulgated modern humans into existence, it has been met with much criticism, and he has gone to great lengths to respond to them. He has furthered the debate on the ethics of procreation

coauthoring an anti-natalism–pro-natalism debate with David Wasserman, *Debating Procreation: Is It Wrong to Reproduce?* (Benatar and Wasserman 2015), and coediting *Procreation and Parenthood: The Ethics of Bearing and Rearing Children* (Archard and Benatar 2010).

The Second Sexism

Professor Benatar’s (2012) book *The Second Sexism: Discrimination Against Men and Boys* has also courted much controversy. In it, he presents the case that there are ways that male humans suffer unjust and unfair discrimination (the second sexism). Accordingly, what makes the second sexism so hazardous is how ubiquitous it is and yet how oblivious people are of it. The second sexism, as Benatar conceptualizes it, is not the result of some intentional malignant effort or design, but has come about as a secondary consequence of the evolutionary process from which the species has emerged and is thus fundamentally a manifestation of sex differences.

The bedrock of this argument is the undervaluing of male lives, as demonstrated by several examples, such as the historical and present exemption of women from conscription into the vast majority of the world’s militaries, higher rates of violence against men (perpetrated by both women and men), preferential placement of women in lifeboats on sinking ships, education disparities favoring women and girls, less severe criminal punishments for women including lack of corporal punishment, favoring of maternal rights over paternal rights in child custody cases, and near universal shorter life expectancies for males (Benatar 2012), especially in times of resource scarcity (e.g., Grayson 1993). These can be considered social manifestations of evolved mechanisms that value female lives over male lives. This depreciation of male lives is likely the product of the minimal reproductive investment required by males compared to females. Males have greater potential reproductive outcomes (in terms of sheer quantity of offspring) than females because of the differing required investments to reproduce. Given an

equal but uncapped number of mates, one man, due to his minimum reproductive investment, could produce many more genetic offspring than one woman. Thus, females have greater mate discretion and receive greater protection because of their lower individual reproductive potentials. This is consistent with the discrepancy between the male–female birth ratio (slightly favoring males) and the male–female population demographic (favoring females).

Although Professor Benatar has carefully crafted the case demonstrating the second sexism, he has not been free from significant criticism. He has fully acknowledged the presence of wrongful discrimination against women and girls and the harm that it has caused and prefaces his book as purposed toward forwarding egalitarian gender equality. To acknowledge wrongful discrimination against one sex is not to deny the existence of wrongful discrimination against the other sex. At this juncture is where much opposition exists, mostly from “partisan feminists” (Benatar 2012, p. 15), whom he contends are interested primarily in advancing and benefiting women and girls rather than promoting gender equality. Benatar has attempted to advocate the complete equality of sexes by acknowledging all instances of wrongful discrimination, against both sexes. Uncontroversial as this premise has been presented, it has not been consequently reflected in the response to the work.

Inconsistencies in Sexual Ethics

Other work in sexual ethics includes a comparison of a promiscuous (or casual) view of sexual ethics and pedophilia and rape. Benatar (2002) has outlined the logical inconsistencies between endorsing a promiscuous view of sex and condemning pedophilic sex and rape. Benatar has carefully elucidated how regarding sexual intercourse as a pleasure to be pursued as any other and not according it special consideration leaves insufficient grounds for condemning iterations of sex (in this case, pedophilia and rape) as abhorrent. Accordingly, if one takes a casual view of sex, no form of sex need be accompanied by

stigma or even condemnation. By his reasoning, if sex is not ascribed romantic or other significance beyond pleasure, as a casual view would imply, then sexual deviations need pose no greater condemnation than gastronomic preferences. In providing evidence to support this conclusion, Professor Benatar has also deflated counterarguments that attempt to reconcile these inconsistent opinions. For instance, the claim that pedophilic sex is condemnable because it can physically hurt the child can be dismissed by focusing on non-penetrative forms of sexual interaction or contact with willing children. Although there are empirically documented effects of childhood sexual abuse on children (e.g., Kendall-Tackett et al. 1993), evidence is also inconclusive about the extent of psychological harm to the child and whether it is due exclusively to the act itself, or rather from secrecy and societal mores prevailing the activity (e.g., Malón 2015; Rind and Tromovitch 1997), or some combination thereof. Indeed, much less evidence is available about the impact of sexual encounters between “consenting” children and consenting adults (although debate surrounds the definition and veracity of “consent” in adult–child sex, e.g., Abel et al. 1984; Ehman 2000). However, if a child is a willing participant, Benatar concludes that a casual view of sex should permit this as parents would permit a child to engage in other activities that they enjoy with adults that carry some risks, such as playing sports.

All of this considered, Benatar furthers the argument that for a person who holds the casual view of sex, rape might be an unnecessarily inflated concept, as it is not taking anything more important than one who deprives gastronomic pleasures. While rape can be considered wrong according to this sexual ethic because it is still bypassing the victim’s desires, it is no more serious than forcing someone with an aversion to tomatoes to eat a tomato. Although he initially does not mention how long-term consequences of rape, such as the possibility of unwanted pregnancy, injury, and disease, increase the consequences (and thus seriousness) of rape even according to the casual view, these additional considerations do not make the rape itself more

condemnable, but only in ad hoc evaluation of the event as subsequent tangential harms. For this argument, rape might thus be better juxtaposed to a nonsexual physical assault that causes lasting physical damage. Rape could thus be considered condemnably as it is opposing the physical rights of another person, but not to any greater degree than a robbery and battery. Insofar as both crimes are serious, according to the casual view of sex, one need not be considered more grievous than the other unless it causes greater bodily harm. Thus, a rape is considered more serious than battery when it results in impregnation or the transmittal of a disease and the battery results in only minor contusions. Similarly, a battery could be considered more serious than a rape when it results in broken bones and the rape results in no major physical injuries. When making such specific evaluations in concert with a casual view of sex, Professor Benatar has indicated it would also become necessary to scrutinize the sexual history of the victim to understand the value she places on sex and thus the magnitude of the rape to her. Thus, a rape might be considered worse for a woman who holds a significant view of sex than a casual view. In this way, only in the significant view of sex, in which sexual intercourse is accorded additional consideration as a special pleasure, can pedophilia and rape be considered particularly immoral as violations of this special act. This view assigns a value to sexual acts that makes condemnation of variations, with either unwilling parties, individuals incapable of appreciating the romantic aspects that make it a special kind of pleasure (e.g., children), or even casual consenting adults, consistent. Whether this condemnation is warranted, Benatar has left up to individual interpretation.

Nonhuman Animals

Professor Benatar is a noted vegan and advocate of animal rights. He has forwarded many arguments that eating meat is morally wrong and should be avoided. Benatar (2001) has surmised that many humans place a greater value on the gastronomic pleasures of meat eating than on the

suffering inflicted upon animals commercially bred, reared, and killed for consumption. It follows that the relatively minor pleasure of eating meat is not commensurate to the pain experienced by the consumed animals. Although he acknowledges that being omnivorous was certainly an important evolutionary development, meat is no longer a necessary part of the modern human diet as the nutrients abundant in meat can also be found in other food sources. Lacking the dietary compulsion to consume meat, Benatar has argued that humans continue to eat meat primarily for culinary pleasure, made possible by a devaluing of the suffering of nonhuman animals. This devaluing of animal suffering has produced subsequent blanket approbation for experimentation on animals. He contends that humans have evolved a priori acceptance of animal consumption leading to de facto acceptance of animal experimentation, with the tendency to make speciesist evaluations of the value of suffering to the animals (Benatar 2000). Thus, he has pointed out that because humans continue to underappreciate the suffering of nonhuman animals, the benefits to humans versus the immediate costs to laboratory animals must be more carefully weighed when evaluating the morality of animal experimentation.

Affirmative Action

In addition, David Benatar has written extensively about affirmative action in his native South Africa, arguing against the inclusion of race as a criterion for determining preferential consideration, especially in hiring or admissions to universities. He has outlined four types of affirmative action: “equal opportunity affirmative action,” which seeks to guarantee that discrimination (especially by race) does not inhibit opportunities for any individual (which he believes no reasonable person would oppose); “tie breaker,” whereby all other qualifications being equal, preference is given to the candidate from a designated (usually racial) category; “strong preference,” where deficiencies in other qualifications can be overlooked when candidates possess the

designated racial designation; and “quotas,” whereby a certain number of positions are set aside and only open to candidates who meet the designated racial criterion (Benatar 2007). The more weight one assigns race, the less weight can be afforded to other more relevant qualifications. While acknowledging the need to address historical wrongs that have left some individuals unjustly disadvantaged, Benatar argues that race is a poor proxy for disadvantage and that considering it as such continues to perpetuate the very apartheid-era stereotypes it exists to counter. For instance, he has argued that “black” academics need no preferential hiring at universities because their abilities have already conferred on them the desired qualifications for employment (Benatar 2007). Even if they were previously disadvantaged, having secured doctoral training and degrees, they no longer need the assistance of affirmative action to achieve positions in academia. He has participated in a lengthy written and panel debates on the subject at the University of Cape Town.

Conclusion

Although controversial, Professor Benatar’s commentaries have appeared in many popular media including the *Cape Times* and online and radio media such as “The Species Barrier” and “Politicsweb.” He has published in many academic journals, including *The Lancet*, *QJM: An International Journal of Medicine*, *American Philosophical Quarterly*, *Ethics*, *American Journal of Bioethics*, *Social Theory and Practice*, *British Medical Journal*, *Public Affairs Quarterly*, and *American Journal of Bioethics*, among others. He remains active in conducting research and publishing about the philosophy of ethics.

David Buss

David M. Buss

Department of Psychology, University of Texas at Austin, Austin, TX, USA

Definition

One of the founders of evolutionary psychology, author of *The Evolution of Desire: Strategies of Human Mating* and *Evolutionary Psychology: The New Science of the Mind*.

Introduction

David Buss is one of the founders of the modern field of evolutionary psychology. He is the most heavily cited evolutionary psychologist in the world, according to Google Scholar (48,773 scholarly citations as of December, 2016). He is widely known for his scientific contributions to understanding human mating strategies, subsumed under the label *Sexual Strategies Theory*. He has made contributions to personality psychology, personality and social interaction, adaptive individual differences, tactics of manipulation, sexual conflict, stalking, sexual violence, and homicide. He authored or co-authored three other evolution-based theories: *Strategic Interference Theory* (Buss 1989a), *Error Management Theory* (Haselton and Buss 2000), and *Homicide Adaptation Theory* (Buss and Duntley 1998; Duntley and Buss 2011). He created these interdisciplinary scientific bridges during an era when evolutionary biology was almost entirely absent from the field of psychology.

Buss's Personal Journey to Evolutionary Psychology

Buss's fascination with understanding human nature – what motivates people and how to characterize their basic mechanisms of mind – began as an undergraduate at the University of Texas at

Austin (1971–1976). He opted to major in psychology, believing that this was the discipline that offered the greatest promise for his quest. Over the course of several years, he became discouraged. All existing theories in psychology seemed somewhat arbitrary. Why, for example, would the human mind be designed to experience cognitive dissonance, intolerance of ambiguity, a desire to enhance self-esteem, or any of the dozens of “effects” or phenomena psychologists had documented? The proliferation of dozens of mini-theories in psychology, none connected to any of the others, seemed scientifically unsatisfying. Lacking was a non-arbitrary set of fundamental premises on which a science of the mind could be built. This quest for explanations anchored in deeper origins ultimately led him to evolutionary theory.

Buss first encountered evolutionary theory in an undergraduate geology class, and theories of cosmology and stellar evolution in an astronomy class. They captured his intellectual imagination. He was awed by the fact that there existed theories designed to explain the origins of things, life in the first case and the universe in the second. During this period, Buss read a book called *The Imperial Animal* written by Lionel Tiger and Robin Fox (Tiger and Fox 1971). Although anchored in a now-outdated theory of group selection, Buss saw for the first time that evolutionary theory might offer a non-arbitrary set of foundational premises for the field of psychology. His undergraduate term paper, titled “Dominance/Access to Women” (written in 1975) posited that men have evolved a status-striving motive, the sole reason being that elevated rank gave them increased sexual access to women. Simplistic perhaps, but a start.

In 1976 when Buss sought a PhD program, there existed no evolutionary psychologists and no field called evolutionary psychology. So Buss began graduate school in personality psychology at the University of California, Berkeley, in 1976, believing that this field had as a central goal the development of grand theories of human nature. During his first year, he conducted a study designed to test the hypothesis advanced in his undergraduate paper, although he never published those results. While completing his graduate work

at Berkeley, he focused the bulk of his empirical work on developing *The Act Frequency Approach* (with Ken Craik, his main graduate advisor), but also published articles with Jack Block and Jeanne Block (two of his other mentors) on personality development, and as sole-author (on dominance and activity level). He continued in his spare time to read widely in evolutionary biology and population genetics, including E.O. Wilson's now classic tome *Sociobiology* (Wilson 1975).

His mainstream work in personality psychology made enough of an impact to land Buss his first post-PhD job as assistant professor at Harvard University in 1981. In teaching his first large undergraduate course, *Human Motivation*, he used evolutionary theory as the overarching framework. He also discovered Trivers' (1972) theory of parental investment and sexual selection (in a book on sexual selection theory that he stumbled across at a used bookstore in Cambridge) and Donald Symons' (1979) book, *The Evolution of Human Sexuality*. At the time, Buss was designing an empirical study of married couples and decided to test predictions about mate preferences based on Trivers' theory and articulated in Symons' book.

Around this time (1981–1982), Leda Cosmides, then a graduate student at Harvard in psychology, heard that Buss was teaching a course on human motivation using evolutionary theory. She introduced herself to Buss, and then to her husband, John Tooby, a graduate student in biological anthropology. Cosmides and Tooby were in the process of developing the conceptual foundations of evolutionary psychology, although at the time their only publication was on the evolution of intragenomic conflict (Cosmides and Tooby 1981). Buss's friendship with Leda and John, and his intellectual connection to them and their magnificent work, endured during the subsequent decades and continues unabated. This friendship, in turn, led to meeting Martin Daly and Margo Wilson when they spent a sabbatical year at Harvard. Buss was influenced by Daly and Wilson's (1983) book, *Sex, Evolution, and Behavior*, which contained many novel insights and testable hypotheses unknown to mainstream psychologists (Daly and Wilson 1983).

In 1984, Buss published his first paper on evolutionary psychology, entitled "Evolutionary Biology and Personality Psychology: Toward a Conception of Human Nature and Individual Differences" in the prestigious journal, *American Psychologist*. Although naïve and ill-informed in many ways, it signaled Buss's enduring commitment to understanding species-typical psychology and profound individual differences within a unified conceptual framework.

When Buss was invited to give a talk at Yale in 1984, he decided to take a chance – he presented his first professional talk on the evolution of human mating. In the audience there happened to be the editor of the prestigious journal, *American Scientist*. On his return to Harvard a few days later, he received from him an invitation to write an article on human mating. This led to the lead article, "Human Mate Selection," published in *American Scientist* in 1985. Requests for reprints of this article poured in from all over the world. Buss responded by inviting scientists from 37 cultures to join him in conducting parallel research under the banner "The International Mate Selection Project." Invitations coming on Harvard University stationery probably helped produce the overwhelming positive response from what ended up to be 50 international research collaborators.

In 1984, Harvard promoted Buss to Associate Professor, but he simultaneously received an offer from the University of Michigan of Associate Professor. At the time, the Michigan Psychology Department was ranked as the best in the country. Buss was mostly known for his work in personality psychology. Had Michigan known that Buss's entire research program was in the process of shifting in an evolutionary direction, it is possible they would not have extended the offer. On the other hand, they were well aware of his evolutionary interests and arranged meetings with key evolutionary scientists at Michigan – Barb Smuts, Richard Wrangham, Dick Alexander, Warren Holmes, Bobbi Low, and Randy Nesse.

Shortly after starting his position at Michigan in 1985, he joined this interdisciplinary group and together they formed the *Evolution and Human Behavior* (EHB) group in 1986, funded with a

generous internal grant from a prescient dean. This rich intellectual environment provided Buss with exposure to primatology, evolutionary anthropology, work on nepotism in ground squirrels, and a stream of evolution-minded scientists who saw Michigan as intellectual hub. Yearly EHB meetings became testing grounds for this emerging interdisciplinary science. In 1986, for example, Buss was honored to chair a symposium with the invited speakers W.D. Hamilton, George C. Williams, Mildred Dickemann, Martin Daly, and Napoleon Chagnon. These yearly meetings eventually led to the formation in 1989 of the *Human Behavior and Evolution Society* (HBES) with W.D. Hamilton serving as its first president.

In 1987, Buss was elected to be a fellow at the *Center for Advanced Studies in the Behavioral Sciences* at Stanford. Elected fellows had the opportunity to spend a year at the center and could, if so inclined, propose a special project involving other scientists. Buss proposed “Foundations for Evolutionary Psychology” and proposed that Leda Cosmides co-lead the project with him. The project was one of only the two approved by the center, and in 1989–1990 it came to fruition with Buss reuniting with Leda Cosmides, John Tooby, Martin Daly, and Margo Wilson. One of our goals was to co-author a book on the foundations of evolutionary psychology, and they made some progress in the form of draft chapters. Although that collaborative book never came to fruition, the project morphed, leading Buss to sole-author the first textbook in the field: *Evolutionary Psychology: The New Science of the Mind* (first published in 1998; its 5th edition was published in 2015). At the center, Buss also began to work on his first book, *The Evolution of Desire: Strategies of Human Mating* (published in 1994; revised editions published in 2003 and 2016). Both books, translated into many languages, continue to be widely used in college courses throughout the world.

Evolved Mate Preferences

Although he found initial support for some key hypotheses about evolved mate preferences based

on studies conducted in Cambridge, Massachusetts, Buss was keenly aware that the work, when published, would be controversial. So he delayed publication and spent 5 years gathering additional data from what turned out to be known as the 37-culture study, involving 10,047 participants from six continents and five islands. Participants included those from all major religious groups, political systems, and geographical locations. Although he had advanced the evolution-based hypotheses prior to the study, Buss did not know what to expect. No one had ever conducted a study of that magnitude (now such large-scale studies are more common due to the internet). Prior to the study, when he asked a dozen non-evolutionary scientists from different disciplines to make predictions, not a single one predicted universal sex-differentiated mate preferences. Most expected that perhaps they might occur in western cultures, or perhaps in capitalist cultures, but certainly not universally. Buss regrets not obtaining signed predictions from these scholars, for once the results were published, one common reaction was “I could have predicted that.”

The first wave of results was published in a target article in *Behavioral and Brain Sciences* in 1989 (Buss 1989a). It received 29 commentaries from diverse scholars. Buss found universal desires for some mate preferences – love, mutual attraction, intelligence, dependability, kindness, emotional stability, and good health. The priority people universally placed on love and mutual attraction surprised Buss, since he had been taught that love was a culture-specific emotion invented by some European poets a couple hundred years ago. This finding was a heart-warming surprise, not predicted in advance of the study, and reinforced the importance of science conducted in the context of discovery in addition to the context of hypothesis testing.

The study also discovered some striking cultural variability. The most variable mate preference was for virginity in a potential spouse. The Swedes and French, for example, did not prioritize virginity at all. The Chinese, in contrast, viewed virginity as indispensable in a spouse. Countries such as Ireland and Japan fell in

between these extremes. Although Buss had predicted universal sex difference in the desire for chastity (defined as no prior experience with sexual intercourse), based on the adaptive problem that men, but not women, face regarding paternity uncertainty, men valued it more than women in only 62% of the cultures. The other 38% showed no sex differences. In no cultures did women value virginity more than man. So Buss's evolution-based hypothesis received only partial confirmation, certainly not robust confirmation, which would have required universality or near universality. The findings also showed that evolutionary psychological hypotheses can be falsified, contrary to the oft-repeated but scientifically inaccurate criticism of evolutionary psychology (see Confer et al. 2010).

By far the findings that received the most attention were the discoveries of universal sex differences, precisely as predicted. Men more than women valued cues to fertility. They placed greater importance on physical attractiveness. Appearance contains a bounty of cues to fertility, which, unlike in chimpanzees, cannot be evaluated directly due to ovulation being relatively concealed or cryptic in women. Men also desired younger spouses, supporting a second evolution-based prediction. Fertility is steeply age graded among women, more so than among men, so youth is a powerful cue to fertility and future reproductive potential. Women more than men universally prioritized financial resources, economic prospects, and nearly universally prioritized cues that lead to resources, such as ambition/industriousness and social status.

These basic findings provided the first massive cross-cultural support for a key set of evolutionary psychological hypotheses. In 1989 when they were published, evolutionary hypotheses were widely regarded as speculative, lacking an empirical basis. These findings rendered that view no longer tenable. Since 1989, these basic findings have been replicating in dozens of other cultures using multiple methods. They remain among the most robust psychological sex differences ever documented across cultures. It was an early "success story" for the emerging field of evolutionary psychology and helped spur others to get into the

field. The study became a "citation classic" and as of 2016 has received more than 3,600 scholarly citations.

Tactics of Attraction

Preferential mate choice represents one component of Darwin's theory of sexual selection. The second is intrasexual competition. Qualities that lead members of one sex to best same-sex rivals gain preferential mating access to the other sex. Although Darwin viewed intrasexual competition as primarily one of "contest competition," such as two stags locking horns in combat, it is now widely recognized that the logic is more general – whatever qualities lead to success in intrasexual competition, be they physical brawn or superior social skills, increase in frequency (evolve) because of the preferential sexual access gained by the victors. Moreover, the mate preferences of one sex should theoretically establish the ground rules for intrasexual competition in the other. If women prioritize athletic prowess in a mate, for example, men should compete with each other to beat other men in athletic displays. If men prioritize physical attractiveness and youth, then women should compete with other women to enhance their appearance and display cues to youth.

Buss tested these hypotheses, not in 37 cultures, but in more limited studies involving college students and married couples. The results again robustly confirmed the hypotheses. Moreover, Buss developed the first taxonomy of tactics of mate attraction, which includes 23 distinct tactics, including displays of kindness, devotion, resources, grooming, physical strength, and so on (Buss 1988a; Schmitt and Buss 1996). These studies also discovered unpredicted tactics, such as the display of humor, a topic that has subsequently receive much research attention and theorizing. Although the key sex-differentiated hypotheses received robust support, the unpredicted findings intrigued Buss as well and convinced him of the importance of conducting studies in a "bottom-up" manner in the context of discovery, in addition to the "top-down" manner in the context of testing *a priori* hypotheses.

Derogation of Competitors

Because mate competition is a zero-sum game in which one person's gain in mating comes at a loss to a rival, one can conceive of two general strategies – enhancing one's own attractiveness relative to rivals (tactics of attraction) and rendering rivals less attractive to mates relative to oneself. This logic led Buss to conduct the first empirical studies of derogation of competitors – the tactics that people use to impugn the desirability of their rivals. He developed the first taxonomy of derogation of competitor tactics, which included 28, such as questioning a rival's fidelity, spreading false rumors about sexually transmitted infections, derogating a rival's intelligence, and questioning a rival's sexual orientation (Buss and Dedden 1990). The studies supported the evolution-based predictions about sex-differentiated tactics. Men more than women derogated their rival's resources (e.g., "He drives a poor car.") and physical prowess (e.g., "He told others that his rival was physically weak."). Women more than men derogated their rival's physical appearance (e.g., "She made fun of the size and shape of her rival's body.") and ability to remain sexually loyal (e.g., "told others that her rival slept around a lot").

Other interesting findings, however, were not predicted in advance. Women were more likely than men, for example, to call their competitors emotionally unstable. Men were more likely than women to question their rival's hygiene. Again, this reinforced for Buss the utility of conducting studies simultaneously in a bottom-up manner that allowed discoveries unanticipated, as well as a top-down manner to test *a priori* hypotheses.

Tactics of Mate Retention

Mates gained must be retained to reap the reproductive potential inherent in long-term mate selection. While reading a book called *The Evolution of Insect Mating System* (Thornhill and Alcock 1983), Buss got the idea to study the tactics by which humans guard and retain mates once they have successfully attracted them. This led to the

first set of studies on tactics of mate retention in dating couples and married couples, as well as the first taxonomy of mate retention tactics (Buss 1988b; Buss and Shackelford 1997). Tactics ranged from *vigilance* (e.g., "He called her at unexpected times to see who she was with.") to *violence* (e.g., "He hit the guy who made a pass at his girlfriend.").

Studies of the use and perceived effectiveness of mate retention tactics supported evolution-based predictions about sex differences. Men more than women retained mates through resource displays and gifts; women more than men retained mates by enhancing their physical appearance. But Buss also discovered unexpected and unpredicted findings. Men (both in dating couples and in married couples), for example, were more likely to use the submission and self-abasement tactic, contradicting the stereotype that women are generally more submissive than men. Moreover, tactics involving displays of commitment, love, kindness, and caring were perceived as much more effective at mate retention for men than for women. These two early publications, the first to break ground on human tactics of mate retention, have received more than 1,000 scholarly citations. A short form of the Mate Retention Inventory (Buss et al. 2008) is now widely used in scientific studies and has been translated into other languages (e.g., de Miguel and Buss 2011).

Mate Poaching

Mate poaching – attempting to lure someone who is already in a mating relationship for either a short-term sexual encounter or a long-term relationship – turns out to be quite common (Schmitt and Buss 2001). This should not be surprising in that desirable potential mates are often the objects of intense interest, and so often end up in relationships. Relationship status, however, does not seem to deter all others from attempting to attract them. Together with David Schmitt (Buss' student, then colleague in a collaboration that has now spanned more than two decades), they conducted the first studies of human mate poaching and developed a taxonomy of its main

tactics. Many tactics turned out to be similar to tactics of attraction. But some are unique to the mate poaching contexts, such as befriending the couple in a platonic guise. Another is derogating one partner to the other (e.g., “He doesn’t appreciate you.” or “You are too good for him.”), implying a mate value discrepancy. Mate poaching represents a domain previously unexplored prior to the Schmitt and Buss (2001) study, and the term “mate poaching” has now entered the mainstream scientific lexicon (http://tierneylab.blogs.nytimes.com/2009/08/27/why-poach-anothers-mate-ask-an-expert-or-brangelina/?_r=0).

The Emotion of Jealousy

Jealousy is a commonly experienced emotion in romantic relationships. Yet it was largely ignored by emotion researchers when Buss began studying it. The pioneer emotion researcher Paul Ekman told Buss that jealousy was not really a “basic emotion,” such as fear, anger, and disgust. Instead, it was a “blend” of different emotions. Moreover, jealousy lacks a distinctive facial expression, and this criterion was central to Ekman’s theory of emotions, a view that can be traced back to Charles Darwin himself. Buss argued that criteria for an emotion being “basic” should not require a distinctive facial expression. Indeed, only emotions whose function is signaling or communication should have distinct facial expressions (Buss 2013). Moreover, if an emotion evolved for specific functions, that of contributing to the solution to specific adaptive problems, and shows convergent evidence of “special design” for those functions, then it should qualify as “basic.”

The hundreds of prior studies published on jealousy contained two key problems, according to Buss. First, most scientists viewed jealousy as a character defect, a sign of neurosis or insecurity, or as a profound pathology. Second, almost none of the hundreds of studies on jealousy had explored whether its psychological design differed between men and women. The two exceptions were the writings of Donald Symons (1979), who argued that sexual jealousy was a universal

and obligate emotion in men, whereas it was as “facultative” or context dependent in women (e.g., less strongly activated in the context of polygyny due to the need to get along with co-wives). And Daly et al. (1982) argued that men’s jealousy should focus heavily on the sexual aspects of a partner’s infidelity, whereas women’s should focus more on cues to the loss of commitment and resources.

Following these functional views, Buss sought to test hypotheses about different functional design of jealousy. He collaborated with Drew Westen, Randy Larsen, and Jennifer Semmelroth, and together they discovered strong evidence for hypothesized sex differences in the weighting given to triggers of jealousy. They posited that emotional infidelity was a cardinal cue to the loss of a partner’s commitment for women, whereas sexual infidelity as a key cue to compromised paternity certainty. Although both sexes are clearly upset about both sexual and emotional infidelity in a partner, when forced to choose which is more upsetting the predicted sex differences emerged. Moreover, men showed greater physiological distress to imagining a partner committing sexual infidelity, whereas women showed greater physiological distress to imagining a partner committing emotional infidelity (Buss et al. 1992).

The publication created a firestorm of reactions. Some proposed alternative theories, although the original author of one later abandoned his alternative theory and instead argued that the sex differences were methodological artifacts. Another offered an incoherent “social cognitive” theory that failed to explain known findings, failed to generate novel predictions, led to no new empirical research, and failed to generate any empirical support subsequently. The sex differences in the design of jealousy have been replicated using multiple methods – forced choice, continuous, physiological, fMRI, and behavioral, and among individuals who have and who have not experienced an actual infidelity in their relationships (Buss and Haselton 2005). The sex differences even show up in verbal interrogations of partners suspected of cheating, such as “Do you love her?” and “Did you have sex with him?” (Kuhle 2011). It remains among a small

handful of the most robust psychological sex differences ever documented across multiple methods and multiple cultures. The original 1992 article has become a “citation classic” and currently is one of the 30 most heavily cited article over the past 30 years in all *Association for Psychological Science (APS)* journals.

Strategic Interference Theory

Buss saw the functional emotion of jealousy as part of two larger theories. The first was strategic interference theory (Buss 1989b). He proposed that emotions such as jealousy, anger, and upset become activated when a person’s strategy for achieving a goal was impeded or blocked. A strategy of securing a partner’s sexual fidelity, for example, was impeded by attempts by mate poachers or rivals trying to lure one’s partner for sex or romance. To take another example, a woman’s strategy of exercising “female choice” about when and with whom she consents to having sex would be impeded by a man who pursued a strategy of sexual force or aggression. Strong negative emotions such as anger, jealousy, and upset serve several key functions, according to strategic interference theory: (1) they alert someone to the source of the interference, (2) motivate action to curtail the interference, (3) help to store interfering events in memory, which in turn functions to (4) avoid future episodes of strategic interference.

Error Management Theory

Jealousy turned out to be illuminated by error management theory (EMT), originally developed by Martie Haselton, Todd DeKay, and Buss (Haselton and Buss 2000). EMT is a theory of selection, so it can be applied to any domain of psychology from perception to social interaction. EMT logic can be stated syllogistically as follows:

1. We live in an uncertain world.
2. We experience cues that are only probabilistically related to cost-inflicting or benefit-bestowing events.

3. There are two ways to err – by inferring the existence of an event when it has not in fact occurred and by inferring the nonexistence of an event when it in fact has occurred.
4. If there are recurrent cost-benefit asymmetries in making these two types of errors, selection will favor adaptively biased inference procedures that function to minimize committing the more costly error, even at the cost of experiencing more frequent inferential errors of the less costly variety.

Jealousy illustrates EMT logic. Buss argued that the cost of missing a sexual infidelity that has occurred is typically greater than the cost of mistakenly suspecting an infidelity when none has occurred (Buss 2000). Because infidelities are typically conducted underneath a cloak of intentional secrecy, their existence must be inferred from probabilistic cues. Empirical evidence supports EMT logic applied to jealousy and infidelity (e.g., Buss 2000; Andrews et al. 2008). Haselton and Buss also used EMT to illuminate design features of the male sexual over-perception bias and the female commitment skepticism bias (Haselton 2003; Haselton and Buss 2000). And EMT logic has been used to illuminate a raft of other psychological phenomena, such as the auditory looming bias, the vertical descent illusion, and adaptive biases in a number of domains of social functioning (for a recent review, see Haselton et al. 2016). EMT logic has also been invoked to explain inferential biases about homicidal intent (Buss 2005).

The Evolution of Aggression and Murder

Because differential reproductive success necessarily hinges on reproductive competition, conspecifics are necessarily rivals, albeit in the context of some levels of intertwined reproductive fates and win-win situations (“gains in trade”) that select for adaptations for cooperation in certain contexts. Enhancing oneself relative to rivals is one generic strategy. A second is inflicting costs on rivals. Buss documented these two generic strategies in the context of mate

competition – tactics of attraction and derogation of competitors. In collaboration with Joshua Duntley, Buss extended this argument to murder. They argued, contrary to the Daly-Wilson claims that murder is a by-product of adaptations designed for nonlethal ends (Daly and Wilson 1988), that humans have adaptations for murder (Buss 2005; Buss and Duntley 1998; Duntley and Buss 2011).

Homicide Adaptation Theory (HAT) proposes that humans have evolved a number of distinct homicide adaptations, such as infanticide, intrasexual rival murder, and coalitional killing (warfare). Simply put, killing a rival, killing a rival's offspring, or killing a rival's kin have been extremely effective ways of inflicting massive costs on intrasexual competitors. The accumulating evidence of adaptations for conspecific killing in chimpanzees (Wrangham 1999) leads to the conclusion that some of these homicide adaptations predate the evolution of *Homo sapiens*.

Being killed inflicts severe costs on rivals, far more than merely harming them nonlethally. It terminates any future access to their current mates and future mating opportunities. It harms their children, since lack of an investing parent leaves children vulnerable to abuse and exploitation, sexual and otherwise. It harms the entire kin group of the victim, which becomes weakened. So as soon as homicide entered the human arsenal of strategies of reproductive competition, selection would immediately favor adaptations to prevent becoming a homicide victim. HAT argues that this set into motion a dramatic coevolutionary arms race, with finely fashioned anti-homicide defenses evolving in ratcheting fashion with ever more sophisticated adaptations to commit murder and ever more sophisticated defenses to prevent being murdered.

Buss and Duntley recognized that their theory is controversial; that the existence of coevolved homicide and anti-homicide adaptations does not rule out the likely possibility that some homicides are by-products of “slips” as Daly and Wilson put it, and that the current empirical evidence cannot definitively determine the precise number and full design of homicide adaptations. Nonetheless, they believe that there is sufficient evidence – from the

paleontological skulls and skeletons riddled with unmistakable marks of murder to the psychological and behavioral footprints of “special design” for murder – to conclude that it is far more likely than not that humans have experienced a long coevolutionary arms race that created adaptations for murder and defenses to prevent being murdered.

The Evolution of Personality and Individual Differences

Although most evolutionary psychologists have focused on universal or species-typical adaptations, Buss has made contributions to understanding personality and individual differences within the broader metatheory of evolutionary psychology. He has argued that humans have evolved difference-detecting adaptations, personality assessment mechanisms, that help to solve problems such as determining who will be a good cooperator (e.g., those high on agreeableness), coalition member (e.g., bravery), or hierarchically ally (e.g., those high in surgency or dominance). These difference-detecting adaptations also help individuals to avoid those who are dispositionally cost inflicting, such as those low on agreeableness or high on dark triad traits such as Machiavellianism or narcissism. Those high in narcissism and impulsivity, for example, are more likely to inflict the costs on their partners through infidelity and costs on their friends through poaching their mates. The personalities of other individuals, in short, partly define the “social adaptive landscape” that must be navigated (e.g., Buss 1991; Buss and Penke 2014).

Buss was among the first to highlight the possibility that personality traits might represent “adaptive individual differences” (Buss 1991; Buss and Greiling 1999), reflecting variation over time and space of which strategies are effective. High sensation seekers, for example, might thrive in migratory or novel environments, whereas low sensation seekers might thrive in more sedentary environments.

Finally, two key issues have eluded mainstream personality psychology – how to define

“situations” and how to conceptualize “person-situation interactions.” Buss contributed to both of these issues by defining situations as adaptive problems, the only non-arbitrary way to define situations from an evolutionary perspective (Buss 2009a). The “situation” of confronting cues to a partner’s infidelity can be illuminated by identifying those cues, detecting the presence of a mate poacher, gauging the relative mate value of the mate poacher compared to self, and so on. In short, situations are defined as the adaptive problems encountered and the corresponding evolved psychological mechanisms that render some clusters of cues psychologically salient and other information invisible.

This formulation, in turn, provides a powerful way to conceptualize person-situation interactions. Person-situation interactions come in two main forms: (1) the ways in which person variables, through the processes of selection, evocation, and manipulation, lead to nonrandom exposure to different suites of adaptive problems and (2) individual differences in the strategies deployed toward solving the adaptive problems that people nonrandomly encounter. Buss believes that a more comprehensive evolutionary psychology must include a deep understanding of the evolution of personality and individual differences and anticipates that these formulations may provide starting places for doing so.

Authored Books

In an effort to reach a broader audience for evolutionary psychology, Buss has authored several books. These include *The Dangerous Passion: Why Jealousy is as Necessary as Love and Sex* (2000), *The Murderer Next Door: Why The Mind is Designed to Kill* (2005), and *Why Women Have Sex* (2009, co-authored with Cindy Meston) (Meston and Buss 2009). His two most influential books are *The Evolution of Desire: Strategies of Human Mating* (1994, 2003, 2016) and *Evolutionary Psychology: The New Science of the Mind* (1998, 2004, 2008, 2012, 2015).

The Evolution of Desire. This book represented the culmination of a decade of research by Buss

and a conceptual synthesis of hundreds of studies on human mating by other scientists. It elaborated on Sexual Strategies Theory (Buss and Schmitt 1993) and included chapters on what women and men wanted in long-term and short-term mates, strategies of casual sex, tactics of attraction, causes of sexual conflict and breakups, mating over the lifespan, and harmony between the sexes. The book was first published in 1994; two new chapters were added to a new edition published in 2003; and the book was totally revamped in a thoroughly updated and revised edition, published in 2016. It has received more than 2,000 scholarly citations, has been translated into ten languages, and continues to be widely used in college courses worldwide.

Evolutionary Psychology: The New Science of the Mind While evolutionary psychology began to emerge as a cogent metatheory for psychology in the late 1980s and early 1990s, professors began to offer courses in it. There existed no textbook. One was urgently needed. After getting encouragement from a handful of people to write such a text, and being approached by publishers, Buss signed a contract. He produced the first textbook in the field in 1998. The text provided historical reviews of evolutionary theory and psychological science that converged on their synthesis (Chapter 1: The Scientific Movements Leading to Evolutionary Psychology) and a chapter on the conceptual foundations of this new science of the mind, heavily influenced by the theoretical work of Leda Cosmides and John Tooby (Chapter 2: The New Science of Evolutionary Psychology). Subsequent chapters were organized logically around adaptive problems – challenges of survival, mating, parenting, kinship, and social group living (e.g., cooperation, aggression, status hierarchies). The final chapter called for the evolutionizing of all subdisciplines within psychology, such as cognitive, social, personality, developmental, and clinical; reviewed evolutionary empirical work within each; and ended with a call for a unified field of psychology that eventually could dissolve these somewhat artificial subdisciplinary boundaries.

Adoptions of this text increased with each successive edition, despite roughly a dozen competing texts appearing since 1998. Buss' *Evolutionary Psychology* text remains the most widely used textbook in evolutionary psychology worldwide. It has entered into its 5th edition in 2015 (Buss 2015), with a 6th edition underway. It has been translated into half a dozen languages, including German, Chinese, and Arabic. And it has become a citation classic, with more than 4,000 scholarly citations as of 2016. Through this text, Buss helped the field of evolutionary psychology to grow and flourish, educating undergraduates, informing professors, and attracting new scholars to the field.

Edited Volumes

Buss has edited six volumes, including *Personality Psychology: Recent Trends, Emerging Directions* (Buss and Cantor 1989); *Biological Approaches to Personality* (Buss 1990); *Sex, Power, Conflict: Evolutionary and Feminist Perspectives* (Buss and Malamuth 1996); and *The Evolution of Personality and Individual Differences* (Buss and Hawley 2011). His most influential edited volume, however, is *The Handbook of Evolutionary Psychology* (Buss 2005), logging in at more than 1,000 double-column pages and some 35 chapters. This led to a 2nd edition of the *Handbook* (Buss 2016), which expanded to more than 50 chapters. Both editions contained a foreword by Steven Pinker, a special essay by Don Symons, and an afterword by Richard Dawkins.

The *Handbook* documented the rapidly expanding use of evolutionary psychology in empirical research. It has received nearly 1,000 scholarly citations and helped to document the utility of evolutionary psychology in leading to insights and discoveries about the human mind previously unknown to social scientists. It also documented the utility of evolutionary psychology for far-reaching branches of sciences and humanities, including business and marketing, literary analysis, political science, and the legal profession.

Teaching and Mentoring PhDs in Evolutionary Psychology

Throughout his career, Buss has devoted considerable effort to mentoring the future generation of scientists. Of his 27 PhD students, roughly two-thirds have obtained tenured or tenure-track professorial positions. The Association of Psychological Science (APS) honored Buss with the 2017 *Mentor Award for Lifetime Achievement*. His former students such as Todd Shackelford, Martie Haselton, and David Schmitt, in turn, have produced a number of PhDs in evolutionary psychology and themselves have made major contributions to the field.

Conclusion

The quest for a true science of the human mind has been Buss' lifetime mission. Although more about the human mind remains unknown than known, some of the key foundations for a science of the mind are now in place. Buss likes to believe that he has contributed to the emergence of evolutionary psychology through his conceptual and empirical work, his authored and edited books, and, importantly, through his students.

Definitions

David Edmonds is a philosopher, journalist, author, editor, senior research associate, and documentary maker.

Introduction

David Edmonds was born in 1964. He graduated from Oxford University and went on to earn a PhD in philosophy from the Open University. He subsequently had fellowships in the University of Chicago and University of Michigan. He has since become an influential philosopher and has written, cowritten, and edited 10 books. Additionally, he is a contributing editor for *Prospect Magazine*, a senior research associate at Oxford's Uehiro Centre for Practical Ethics, and an award winning documentary maker for BBC radio.

David Edmonds

David Edmonds' work lies within the philosophy subgenre of practical ethics (Edmonds 2016a). One of his recent books, *Would you Kill the Fat Man?*, which was picked for Editor's Choice in the New York Times, describes the Trolley Problem and its many variations. Beyond simply describing the moral puzzle, Edmonds discusses what the responses to this dilemma indicate about human morality (Edmonds 2013). Edmonds has also written a book called *Caste Wars: The Philosophy of Discrimination* (Edmonds 2006), which discusses the emotional reactions to discrimination and the complexity of "rational discrimination," which is discrimination based on statistical evidence.

Edmonds has also coauthored a number of best-selling books with John Eidinow depicting historical events that impacted the field of philosophy and society more generally. *Wittgenstein's Poker* (Edmonds and Eidinow 2014) describes the 10-min argument between Karl Popper and Ludwig Wittgenstein in Cambridge, and the consequences of this argument for both the field of philosophy and history. *Bobby Fischer Goes to War* (Edmonds and Eidinow 2011) describes the chess match in 1972 between an American, Bobby Fisher, and a Russian, Boris Spassky, which has often been called the most famous chess match of all time. *Rousseau's Dog: A Tale of Two Philosophers* (Edmonds and Eidinow 2007) focuses on the argument between Hume and Rousseau that turned the two philosophers into mortal enemies. Edmonds has also compiled and edited the essays of over 40 philosophers into a single book labeled *Philosophers Take on the World* (Edmonds 2016b). These essays cover topics such as guns, abortion, hatred of sports, and the morality of drinking alone.

Edmonds also produces and co-runs a number of podcasts with Nigel Warburton, a philosopher and freelance writer. *Philosophy Bites*, which has over 30 million downloads, interviews different philosophers for 15–20 min on a specific topic. Past featured philosophers include Peter Singer, Simon Blackburn, and Martha

Nussbaum. Other podcasts that he is involved with include *Free Speech Bites*, which tackles issues of free expression, and *Social Science Bites*, which includes interviews with leading social scientists such as Stephen Pinker and Kate Picket. Interviews from different podcasts have been compiled into a number of books, including *Philosophy Bites*, *Philosophy Bites Back*, *Philosophy Bites Back Again*, and *Big Ideas in Social Science* (Philosophy Bites n.d.).

Conclusion

David Edmonds is a prolific writer whose work has made significant contributions to the field of philosophy, as well as numerous fields of social sciences. His books manage to be digestible for the general public while remaining interesting to other philosophers and academics. If interested, further information on David Edmonds can be found at <http://davidedmonds.info/>.

David F. Bjorklund

Carey Fitzgerald
University of South Carolina Beaufort,
Bluffton, SC, USA

Definition

David Bjorklund is an evolutionary developmental psychologist and Professor of Psychology at Florida Atlantic University.

Introduction

David Bjorklund was born in Worcester, Massachusetts, in 1949. He earned his Bachelor of Arts in 1971 from the University of Massachusetts – Amherst. He continued his education by earning his Master of Arts from The University of Dayton in 1973. He earned his Ph.D. in Developmental Psychology in 1976 from the University of North Carolina – Chapel Hill. After earning his Ph.D., Dr. Bjorklund joined the faculty of Florida Atlantic University. He has also served as a visiting professor at several prestigious institutions – including Emory University, The University of Georgia, James I University, and the Max Planck Institute for Psychological Research.

Career and Contributions

His current research interests include children's cognitive development and evolutionary developmental psychology. Over the past 40 years, Dr. Bjorklund has been awarded over \$700,000 in grants to aid in his research in developmental psychology. His research has focused on a variety of subjects, including cognitive development in children, suggestibility, false memories in children, and mental representations in nonhuman primates.

Dr. Bjorklund has been publishing empirical psychological research for over 45 years. He has published over 130 peer-reviewed articles in the areas of cognitive and developmental psychology.

He has also authored and co-authored several books on the subject of evolutionary developmental psychology – including *Children's Thinking: Cognitive Development and Individual Differences* (2012) and *Why Youth is Not Wasted on the Young: Immaturity in Human Development* (2007) which has been translated into Dutch and Korean, *Child and Adolescent Development: An Integrative Approach* (2012), *The Origins of Human Nature: Evolutionary Developmental Psychology* (2002), and *Looking at Children: An Introduction to Child Development* (1992). Dr. Bjorklund has also edited and co-edited many volumes on this subject as well, such as *Children's strategies: Contemporary Views of Cognitive Development* (1990), *Origins of the Social Mind: Evolutionary Psychology and Child Development* (2005), and *False-memory Creation in Children and Adults: Theory, Research, and Implications* (2000).

Dr. Bjorklund is currently the editor of the *Journal of Experimental Child Psychology*. He was also the associate editor of the journal *Child Development* from 1997 to 2001. He has also served on the editorial board for several peer-reviewed evolutionary psychology journals, including *Evolutionary Psychology*, *Journal of Comparative Psychology*, and *Evolutionary Behavioral Sciences*, as well as many peer-reviewed developmental psychology journals, such as *Developmental Review*, *Journal of Cognition and Development*, *Cognitive Development*, and *Educational Psychology Review*.

Conclusion

Dr. Bjorklund continues to conduct evolutionary developmental psychological research at Florida Atlantic University. He has remained an active professor, scientist, author, editor, and peer reviewer. He currently is the head of Florida Atlantic University's EvoDevo Laboratory, which focuses largely on how the environment interacts with one's genes to influence perceptual development in children. He also continues to teach undergraduate and graduate courses in cognitive development and evolutionary psychology.

David Haig

Manus Patten

Georgetown University, Washington, DC, USA

Synonyms

[Evolutionary biologist](#); [Geneticist](#); [Researcher](#); [Theorist](#)

Definition

David A. Haig is an evolutionary biologist and the George Putnam Professor of Organismic and

Evolutionary Biology at Harvard University. He received his undergraduate and graduate degrees from Macquarie University in his native Australia and later held fellowships at Oxford and Harvard. His work in evolutionary theory spans a wide range of topics, including meiosis, human pregnancy, plant life history, the genetic code, gene selectionism, genetic conflicts, and genomic imprinting.

Introduction

We typically assume that each one of us is just that: a *one*. David Haig's work in evolutionary genetics exposes the flaw in this assumption. His evolutionary theories show how at the genetic level one isn't really *one* so much as *two*. Two genomes, one from mother and one from father, paired together transiently, each an object of natural selection. Although under certain conditions natural selection may favor cooperation between the two genomes during the development of the organism, under others it may foment conflict between them, for what is best evolutionarily for one is not necessarily best for the other. Haig has focused on these internal genetic conflicts and chronicled how natural selection acting at cross purposes on the two halves of the *one* has shaped our genetic system, our development, and our behavior in unexpected ways. He is perhaps best known for his work on the evolution of genomic imprinting and the evolution of imprinted genes in response to such evolutionary conflicts. Haig's perspective, that an individual is divisible into genetic factions, is necessary both for understanding why genomic imprinting evolves and for understanding the forces that have guided the evolution of the human brain and behavior.

The Kinship Theory for the Evolution of Genomic Imprinting

Genomic imprinting is an epigenetic phenomenon known to occur in dozens of genes in the genomes of flowering plants and mammals (Ferguson-Smith 2011). An imprinted gene has a different

expression level depending on its parental origin, which most often manifests as complete silencing of the maternally derived allele and expression exclusively from the paternally derived allele, or vice versa. Imprinted expression is found predominantly in genes expressed in the placenta and brain of mammals and in the endosperm of seed plants. Imprinted genes influence a diverse range of phenotypes, most notably growth and social behavior.

In the late 1980s, these were the known facts of genomic imprinting, and a motley collection of seemingly unrelated facts they were. Haig introduced his kinship theory for the evolution of genomic imprinting, which at once made sense of the various phenotypic effects, the narrow tissue-specificity, and the disjunct taxonomic distribution of imprinted genes (Haig and Westoby 1989; Haig 1997, 2000). He emphasized that in both mammals and seed plants growth depends on resources provided by a mother and comes at the expense of her ability to raise more offspring. Growth is itself a kind of social behavior in both taxa in that it indirectly affects the fitness of kin, and any organ – be it a brain, a placenta, or the endosperm of a seed – that can influence the allocation of limited resources among kin can therefore be an arena for genomic imprinting.

The kinship theory relies on a few reasonable premises to arrive at the evolution of imprinted expression: first, genes of maternal and paternal origin within an individual organism are not equally related to the individual's kin group; second, the optimal phenotypes – i.e., the behaviors or growth patterns that maximize inclusive fitness – are different for maternally and paternally derived genes; third, these phenotypes are sensitive to the gene's total expression level; and fourth, owing to epigenetic cues of parental origin, genes can achieve a different expression level when they are maternally versus paternally derived. If these premises hold, natural selection will favor genes with parental origin-specific expression levels. It is as though the two alleles at a locus take sides according to their parental origin and debate the total expression of the gene through the course of evolutionary time. When one evolves an increased expression level, the

other counters by evolving a decreased expression level. This evolutionary debate proceeds until natural selection has produced a gene that silences itself when inherited from one parent but expresses itself when inherited from the other, at which point the debate ceases (as an allele's expression cannot go any lower than zero).

For example, consider a gene for a growth factor produced by the fetal placenta during a mammalian pregnancy. The gene's increased expression confers growth on the offspring that expresses it at a cost to the mother who provisions him; in other words, the current offspring feeds but future siblings starve. Because of partner switching, the paternally derived allele is less likely than the maternally derived allele to be found in identical copies in these future siblings and so values this mother's future reproduction less than the maternally derived allele does. Natural selection will therefore favor higher gene expression when paternally derived than when maternally derived. In contrast, the maternally derived allele would be passed to the next generation in more identical copies – via the bearer's own reproduction plus that of future siblings – were it to temper the current offspring's growth somewhat. Thus, slight decreases to this gene's expression level when maternally derived would be favored and slight increases when paternally derived would also be favored. The kinship theory predicts that imprinted genes silenced on the maternally derived copy are those that generally enhance growth at the expense of kin and, vice versa, imprinted genes that temper growth are silenced when paternally derived, a prediction that is broadly supported by the data (Haig 2004).

Conflict in the Evolution of Human Behavior

But growth is not the only phenotype over which there may be conflict between the two genomes nor are proteins that pass between fetal and maternal tissues the only armaments available to genes in conflict. A wide range of social phenotypes – e.g., sleep duration (Haig 2014), impulsivity (Dent et al. 2018), and mentalizing ability

(Crespi 2008) – may entail different fitness effects for genes of maternal and paternal origin, and individuals' brains can affect their kin's fitness just as much as individuals' growth. A complete understanding of the human brain therefore requires recognizing that conflict may be widespread during its development and may have been a potent force in its evolution.

Much can be learned about the development and evolution of the human brain through the study of imprinted genes and imprinting disorders. Haig, for example, has studied Prader-Willi syndrome (PWS) to understand features of human behavior and life history (Haig and Wharton 2003). PWS is characterized by low muscle tone, a weak suck, high fatness, excessive sleep in infancy, and hyperphagia starting by about the age of four and a half. It is also associated with an increased risk for psychosis (Buiting 2010). PWS results from an absence of paternally expressed imprinted genes on one small region of human chromosome 15. Interpreted in light of Haig's kinship theory, the PWS phenotype is an overshoot of the maternally derived genome's optimum for these traits (equivalently, PWS can be viewed as an undershoot of the paternally derived genome's optimum); maternally expressed imprinted genes are naturally selected to promote decreased muscle tone, increased fat deposition, prolonged sleep, increased motivation for seeking supplemental foods, and an increase in the mentalizing abilities that become pathologically exaggerated in schizophrenia. Angelman syndrome (AS) is another imprinting disorder that, in contrast with PWS, results from the absence of a maternally expressed imprinted gene from the same region of chromosome 15. Children with AS display almost the opposite traits as those with PWS. They are hyperactive and hypertonic, they sleep less than normal children, and they have an increased incidence of autism (Buiting 2010).

That there are diametrical disorders such as these, which result from the over- or under-expression of imprinted genes, lends support to the kinship theory for the evolution of genomic imprinting (Úbeda and Wilkins 2008); the kinship theory ably predicts the opposite effects resulting

from the loss of expression of maternally or paternally expressed imprinted genes. Further, these disorders have inspired a view of the normal brain as lying on a spectrum between two extremes, each of which corresponding to a disease state that results from the overshoot of some genomic faction's optimum (Crespi 2013).

The novel perspective that emerges is one of genes clashing evolutionarily over how the brain should develop. The kinship theory, with its emphasis on the asymmetric relationships between maternally and paternally derived genomes to other kin, provides the evolutionary rationale for why there would be such battling within the individual during development, and it identifies the warring factions. It leads to the view that normal development results when these warring factions reach not a détente – for harmonious conflict resolutions are difficult to evolve – but rather an impasse. A normal brain is one where the opposing hostilities balance each other. Perhaps the most intriguing extension of Haig's kinship theory logic is to normal variation among humans. In principle it is possible that normal variation in human behavior and personality is the result of slight imbalances in the expression of genes that when greatly imbalanced lead to disease states (e.g., Goos and Silverman 2006; Crespi et al. 2018).

Conclusion

Haig's kinship theory does more than offer an explanation for a seemingly obscure epigenetic phenomenon. Like natural selection itself, it provides a new lens through which to view nature and bring into focus the logic of its design. The implications of Haig's kinship theory for evolutionary psychology are far-reaching. The theory suggests that normal behavioral phenotypes result only when a balance is achieved between the opposing pushes and pulls of maternally and paternally expressed imprinted genes during development. The theory also underscores how the evolution of these phenotypes and others has been shaped not only by selection on the organism itself but also by selection on the genes within it. We should recognize that each one of us contains genetic

factions, each of which are the targets of natural selection, and that the individual that results has been designed with their interests in mind as much as ours.

David Wasserman

Lisa L. M. Welling
Department of Psychology, Oakland University,
Rochester, MI, USA

Definition

David Wasserman is the former Director of Research at the Center for Bioethics at Yeshiva University. He is currently on the faculty at the Department of Bioethics of the National Institutes of Health. He specializes in ethical issues related to reproduction, reproductive technology, genetics, neuroscience, and disability.

Introduction

David Wasserman began working in the Department of Bioethics at the National Institute of Health in 2013. He serves on the editorial boards for the journals *Ethics* and *Journal of Applied Philosophy* and is a Fellow of the Hasting Center for Bioethics (National Institute of Health 2019). He is also the Vice President of the Society for Philosophy and Disability and a member of the American Philosophical Association, the APA Committee on Law and Philosophy, the American Society for Bioethics and the Humanities, and both the District of Columbia and New York Bar Associations. He was previously the Director of Research at the

Center for Ethics, Yeshiva University (National Institute of Health 2019). Wasserman has made significant written contributions to the field of bioethics, with particular attention paid to ethical issues in reproduction, reproductive technology, neuroscience, health care, genetics, and disability. His many publications include two co-authored books (*Disability, Difference, Discrimination: Perspectives on Justice in Bioethics and Public Policy* (Silver et al. 1998) and *Debating Procreation: Is it Wrong to Reproduce?* (Benatar and Wasserman 2015)) and four co-edited volumes (*Genetics and Criminal Behavior* (Wasserman and Wachbroit 2001); *Quality of Life and Human Difference: Genetic Testing, Health Care, and Disability* (Wasserman et al. 2005); *Harming Future Persons: Ethics, Genetics, and the Nonidentity Problem* (Roberts and Wasserman 2009); and the *Oxford Handbook of Philosophy and Disability* (Wasserman and Cureton in press)).

Education and Career

David Wasserman earned a Bachelor of Arts in Philosophy from Yale University in 1975. He went on to earn a Juris Doctorate at the University of Michigan in 1978 and a Masters of Arts in Psychology at the University of North Carolina in 1984. Thereafter, he was an Assistant Professor and Director at the University of Connecticut School of Law (1984–1985), a Senior Staff Attorney in the Criminal Appeals Bureau for the Legal Aid Society (1981–1986), a Fellow at the New York University School of Law (1986–1988), a Fellow in Ethics and the Professions at Harvard University (1988–1989), a Research Scholar at the Institute for Philosophy and Public Policy at the University of Maryland (1989–2007), and the Director of Research at the Center for Ethics at Yeshiva University (2007–2014; Wasserman 2019). He is currently on the faculty at the Department of Bioethics of the National Institutes of Health, where his work focusses on the ethics of reproductive technology, genetic research and technology, health care, and disability.

Books and Edited Volumes

In addition to numerous articles and book chapters, David Wasserman has co-authored two books and has co-edited four books (three published, one forthcoming). Along with Anita Silvers and Mary Mahowald, Wasserman outlines current issues in bioethics in *Disability, Difference, Discrimination: Perspectives on Justice in Bioethics and Public Policy* (Silver et al. 1998). Specific topics, covered in the context of the Americans with Disabilities Act of 1990, include genetic discrimination, the so-called heroic treatment of impaired neonates, and euthanasia and assisted suicide among the severely disabled. The book includes three essays (one each by Silver, Wasserman, and Mahowald) where each author takes a different philosophical stance (libertarian, liberal, and egalitarian feminist, respectively) and where each essay is followed by criticisms by each of the other authors. Wasserman argues in favor of distributive justice approach that aims to balance the social tasks of either correcting people's disabilities or accommodating them in order to accomplish equality and full social participation of all people.

Wasserman followed his initial book with three edited volumes that similarly debate ethical issues related to genetics, disabilities, and reproduction. In 2001, he co-edited, along with Robert Wachbroit, a volume titled *Genetics and Criminal Behavior* (Wasserman and Wachbroit 2001). Contributing philosophers discuss important ethical considerations raised by genetic research into criminal behavior. Wasserman followed this edited volume with another titled *Quality of Life and Human Difference: Genetic Testing, Health Care, and Disability* (Wasserman et al. 2005), which discusses health policy, ethics, and social issues raised by prenatal testing for disability over nine essays. A third edited volume, titled *Harming Future Persons: Ethics, Genetics, and the Non-identity Problem* (Roberts and Wasserman 2009), is comprised of 16 chapters that cover the ethical obligations we have with respect to future persons and offspring and the ethical implications of our actions on future generations. Contributors specifically discuss the nonidentity problem, which is a paradox within population ethics involving the

inability to hold three views simultaneously: (1) that an act can be wrong only if that act makes things worse for or harms an existing or future person (i.e., the person-affecting view), (2) that an act that confers on a person a flawed existence is not bad for that person if the person could never have existed without that act, and (3) some acts that bring a person into existence are wrong even if not wrong for someone (see Roberts 2019).

Continuing his work on ethical considerations surrounding procreation, Wasserman teamed up with David Benatar to co-author *Debating Procreation: Is it Wrong to Reproduce?* (Benatar and Wasserman 2015). In this book, Benatar and Wasserman take contradictory views on the ethics and permissibility of reproduction. Benatar takes an anti-natalist perspective by arguing that reproduction is always morally wrong because, according to Benatar, coming into existence in and of itself always causes a serious harm to the individual. Benatar further contends that even if existence were not always harmful, the risk of harm is sufficient as to make procreation always wrong. Moreover, he asserts that because humans are defective and cause harm on a large scale (e.g., environmental harm, pain, and suffering to other living beings) that it is unethical to create more of them. In contrast, David Wasserman defends procreation with a series of moderate pronatalist arguments that describe procreation as permissible, but not required. Wasserman begins by criticizing what he views as the overreliance of anti-natalists on the argument that the avoidance of harm is more important than the accrual of benefits. He goes on to outline several pronatalist arguments that he believes should be only somewhat constrained based on the well-being of the future child (see also, e.g., Wasserman 2005). Wasserman maintains that the expected good of a future child and of the parent-child relationship can justify procreation, even in the face of expected adversity (e.g., disabilities).

Most recently, Wasserman co-edited the *Oxford Handbook of Philosophy and Disability* (Wasserman and Cureton in press). This edited volume features contributions by several prominent philosophers who summarize and discuss

ethical views of disability. Example topics include social inclusion, justice, reproductive choice and technology, moral and social status, neuro-technologies, discrimination, and parental autonomy, among others. This most recent work expands on the topics Wasserman specializes in (e.g., reproductive technology, bioethics, disabilities) by applying philosophical and ethical perspectives to contemporary issues.

Conclusion

David Wasserman has made and continues to make important contributions to the field of bioethics and related disciplines. His extensive written work on ethical issues surrounding disability, reproduction, genetics, biotechnology, neuroscience, and health care advances discussion on these topics in ways that can potentially inform public policy (e.g., Wasserman 1998) and encourage discourse (e.g., Benatar and Wasserman 2015).

Day Care

Noam Shpancer
Otterbein University, Westerville, OH, USA

Definition

A place, facility, program, or organization that takes care of children during the day, usually while their parents are at work.

Synonyms

[Daycare](#); [Nonparental childcare](#)

Introduction

The number of US children who spend time in daycare has risen markedly in the past four decades (Johnson 2017). Currently, six million children under three-years-old are in nonparental care. A majority of US children will spend time in some form of nonparental care before age five (Zero to Three 2017).

While nonparental childcare is, statistically speaking, a current cultural *norm*, it has not

quite eclipsed stay-at-home parental care as a cultural *ideal*. Therefore, while 62% of mothers with infants are in the labor force, working American mothers still contend often with ambivalence, guilt, and social attitudes that may characterize them as less warm and committed than stay-at-home mothers (Brescoll and Uhlmann 2005).

As nonparental childcare has grown, child development researchers have become increasingly invested in learning about the implications of this form of care for children, their parents, and society at large. Early daycare research focused mostly on comparing home-reared and daycare children, looking to address fears that nonparental care might harm young children by disrupting their attachment relationships with their parents, undermining parental influence, or stunting their emotional and intellectual development. Early researchers were also interested in whether professional child caregivers could develop deep, nurturing bonds with the children in their care to provide them with quality interpersonal experiences necessary for healthy development.

In recent decades, with accumulating evidence showing that the “home-reared” and “daycare reared” labels were not in themselves predictive of developmental outcome, research has begun to focus on mapping how child and parent characteristics, environmental conditions, and the cultural milieu interact to produce developmental outcomes in children across care arrangements. We understand today that child development occurs and should be understood and studied in a multidimensional context, where both proximal (e.g., the home and daycare environments) and distal (e.g., governmental childcare policies; parental work stress) conditions interact to shape developmental trajectories. Concurrently, the old *nature vs. nurture* formulation has been supplanted by the understanding that children’s development and adjustment are shaped by *both* genetic and environmental influences in a complex, interactive dance (Shpancer 2006).

Daycare Research: Methodological Difficulties

Daycare research is not easy to conduct or interpret. True experimentation is not usually feasible due to ethical constraints (researchers cannot force a group of parents, chosen at random, to care for their children in a particular way). In the absence of true experimentation, cause and effect relationships are difficult to discern. In addition, genetic and environmental influences on child development are often correlated, which makes the task of teasing them apart challenging. For example, highly anxious parents may transmit the genetic make up for anxiety to their child and also practice an overprotective caregiving style. Moreover, different individual children select different environmental niches based on their temperamental tendencies. A hyperactive child will not likely choose to spend time in the library. His poorer academic performance may correlate with low library attendance, but his genetic makeup may be the cause for both his low attendance and his poor academics.

To complicate matters still, recent studies have suggested that children are differently predisposed genetically to being influenced by their environment, including the daycare environment. Some children are thus more prone to suffer adverse effects in daycare because their genetic endowment renders them more reactive to environmental stress. Such genetic individual differences may explain some of the inconsistency of findings in research on children’s adjustment in daycare (Belsky and Hartman 2014).

Finally, the results of daycare research are often open to competing interpretations, some of which may be guided by sociopolitical considerations far removed from – and at times hostile to – the jurisdiction of science (Crosnoe and Leventhal 2016). For example, if maternal employment is found to place some infants at higher developmental risk, how much child risk is our society willing to accept in the name of protecting mothers’ right to pursue financial independence and professional fulfillment (both of which may

confer benefits on their children later on in development)? No surprise then that daycare research has been at times both a contentious and a mad-deningly inconsistent field of inquiry.

Daycare Research: Consensus Findings

Still, the literature has converged onto several consensus conclusions. First, an emerging consensus in the literature is that daycare attendance does not inherently disrupt optimal child development and parent-child attachment relationships (Belsky et al. 2007; NICHD Early Child Care Research Network 1997). Second, family variables are, by and large, more predictive of child development than daycare variables, even for children who spend significant time in daycare (Shpancer 2006). Third, caregivers can indeed develop close, secure attachments with the children in their care, independent of parent-child attachment (Goossens and van Ijzendoorn 1990).

Another consensus for daycare researchers has crystalized around the importance of care quality. High-quality daycare has been shown to improve early learning, cognitive, language, and socioemotional development, as well as school achievement, with some effects lasting into adolescence and beyond (Child Care Aware of America 2017; Vandell et al. 2016; Zero to Three 2017). High-quality nonparental childcare may also serve as a protective factor for children from disadvantaged, chaotic home environments (Berry et al. 2016). High-quality care, of the kind that is associated with developmental gains for children, includes warm, responsive, and engaged caregivers; a safe and stimulating environment; and structured educational activities (Brooks-Gunn 2017).

Daycare: Lingerin Concerns

At the same time, concerns and challenges remain for daycare children (and their parents). First, research has shown quite consistently that under

some circumstances, particularly maternal insensitivity and low-quality daycare, extensive non-parental care in infancy predicts higher risk of disrupted mother-child attachment (Hazen et al. 2015).

Another cause for concern has been the persistent suggestion from the research that children who spend much time in daycare exhibit more externalizing (noncompliance) problems, particularly if they spend many hours in low-quality care and in large groups of peers (McCartney et al. 2010). These increases, it should be noted, tend to be mild, and they do not replicate well in non-US samples and when more rigorous designs are used (Dearing and Zachrisson 2017).

Daycare children, particularly younger ones, also experience a rise in respiratory tract and other infections, mostly upon entry to daycare (Schuez-Havupalo et al. 2017). Research has also found elevated levels of the stress hormone cortisol in children attending daycare (Groeneveld et al. 2010). Higher cortisol is of interest in part because of its association with poorer executive function in children. The long-term developmental implications of this finding are not yet clear, but research has suggested that multiple factors, such as daycare quality, caregiver competence, parent-child attachment, and parental social support may moderate this pattern (Wagner et al. 2016).

Another point of concern emerging from the research is that while parents by and large report satisfaction with their daycare arrangements, most daycare programs in the US today do not meet criteria for high quality (Child Care and Health in America 2016; NICHD Study of Early Child Care and Youth Development 2006). The mediocrity of daycare quality in the USA is troubling particularly in light of accumulating evidence showing that developmental gains for daycare children occur quite exclusively in high-quality settings (Peisner-Feinberg et al. 2001).

Alongside persistent concerns about quality, another fundamental concern regarding the daycare system in the USA is affordability.

Daycare in the USA – particularly formal, center-based high quality care of the kind that is associated with developmental gains for children – is pricy, costing as much as 12,000 dollars per year depending on the state. The average cost of infant day care may be as high as \$17,000 per year (the younger the child the more expensive the care, in part because caregiver-child ratio is smaller for younger children). The average cost of keeping an infant in center-based care is higher than college tuition in most states (Zero to Three 2017). Cost is the most commonly reported obstacle for families seeking childcare. Daycare costs have risen roughly 70% between 1985 and 2012 (Child Care and Health in America 2016; Laughlin 2013). High-quality daycare is currently out of reach for many poor and even middle-income families (Whitehurst 2017). Families therefore often must rely on relative care or a patchwork of informal unregulated arrangements of middling quality.

Conclusion

Daycare for infants and young children is normative in today's America. A majority of families with young children will at some point choose to use nonparental childcare services. Working parents need and want – and their children surely deserve – high quality, accessible, and affordable daycare. Spending time in safe, stimulating, and stable environments with properly educated, caring, and fairly compensated daycare professionals will facilitate most children's progress on the path to becoming well adjusted and productive adults (Brooks-Gunn et al. 2016). Thus, high-quality daycare is a sound social investment, and the return on investment in the early years is greater than what we typically get for intervening in later years (Brooks-Gunn, 2017; Karoly 2016). Unfortunately, the current state of American daycare is far from optimal. Too many daycare facilities lack in quality. Too many families lack education about, and access to, high-quality daycare. Figuring out how to solve these problems is an urgent challenge to which our society is yet to rise.

Death

Colin Feltham

Sheffield Hallam University, Sheffield, UK

Synonyms

Extinction; Fatality; Mortality; Phenoptosis; Senescence; Thanatology

Definition

The irreversible cessation of all biological functions in individual organisms. A high degree of consensus focuses on cessation of pulse, breathing, brain activity, and personhood as defining characteristics of clinical death in human beings.

Introduction

Death is a phenomenon most human beings above the ages of about 4–7 “understand” and think about somewhat (Talwar et al. 2011), and medical science is largely clear about it, if with some caveats (Laureys 2005). But we retain diverse cultural and religious views on the theory and actuality of death and dying, while its universality is reflected unevenly in interdisciplinary sources on the topic. In one of the first edited, interdisciplinary, systematized collections on the subject, Feifel (1959) remarked how little was known; this was despite Weismann’s (1889) seminal work on programmed death. Death here is taken to be the complete and irreversible cessation of biological functions, indeed all functions of the individual. Religious and hypothetical concepts of an afterlife or “noncorporeal continuance” are not considered extensively but recent work in resuscitation science suggests loss of vital signs may not be accurately deemed the customary “moment of death” (Parnia 2014).

In the interests of semantic and developmental clarity, we might argue that *dying* is first characterized by massive sperm elimination before conception. Miscarriage and stillbirth remain significant losses, as do experiences of sudden infant death syndrome. For those who grow old and have a “standard death,” a life entails a chronic process of risks from early intrauterine existence onward, and apoptosis that accompanies the entire life course (Shields 2008), punctuated by individual biomarkers of aging and major transitions like menopause, accelerated molecular damage (Salinari and De Santis 2015), and finally to terminal diagnosis and end of life care. In the final stages, breathing slows, death rattle (terminal respiratory secretions) may occur, heart stops

(*clinical death*), and minutes later brain death signifies the moment of expiry, when urination or defecation may occur. Confirmation of loss of vital signs is given (*legal death*), and decomposition by autolysis (self-digestion) proceeds within minutes.

Just as biological age differs from chronological age between individuals (Simm et al. 2008), subjectively we may all feel younger or older than the supposed norm for our age, and the sense of mortality varies (Diehl et al. 2015). The “oldest old” (over 95) are often very ready for death or welcome it (Fleming et al. 2016), and even many younger but depressed, or badly disabled, people confront religious or statutory prohibitions on seeking assistance with voluntary dying.

Worldwide, approximately 57 million human beings die annually (Spellman 2014) and by most estimates about twice as many are being born. Causes of death worldwide are categorized in specific medical etiologies and circumstances, including cardiovascular disease and cancers, through infections, malnutrition, accidents, suicide, murder, executions, and mass disasters (Lozano et al. 2012). Average lifespan in the Paleolithic was 33; in early modern England (sixteenth to eighteenth centuries) 33–40; in the 1950s worldwide it was 48; and in 2010 it was 67.2. Today life expectancy varies by gender, ethnicity, region, and other factors but in the USA in 2014 was 78.94 (76.6 male to 81.4 female). In the USA in the 1850s infant deaths (below age 5) ran at an estimated 216 per 1000 but in 2014 were recorded as 582 per 100,000. The oldest documented person worldwide was Jeanne Calment (1875–1997) who lived to 122. Fogel (2004) charts the rise of life expectancy across the past 400 years. The *Hayflick limit* and other measures suggest a natural upper limit to human life spans based on telomere shortening in chromosomes (Burnet 1974; Dong et al. 2016; Mueller and Rose 1996). Volk and Atkinson (2008) estimate that prior to the last 200 years, approximately 50% of children died by the age of one and 80% by the age of 18.

In the widest context, the universe had a beginning and will have an end dictated by entropy (Impey 2010). All forms of matter are subject to

change and it is estimated that the vast majority of species have become extinct. Indeed, constant biological turnover from cells through to all species is unavoidable. *Homo sapiens* are subject to the same principles but appear to be the first species in which each individual is aware of his or her unavoidable future death. One estimate of how many people have ever lived (and therefore died), taking *Homo sapiens* to commence 50,000 years ago (this figure is often put at 200,000 years), is 108 billion.

Scientific Aspects of Death

Sometimes known as thanatology, the scientific study of death includes aspects of physics, chemistry, biology, and medicine. Howard (2016) after Schrödinger, reminds us that animals convert solar energy (light) into heat, as part of a universal entropic principle: animals must work to survive, to exist instead of succumbing to nonbeing, and in this process life generates constant turnover, complexity, and chaos. Clark (1996) charts a path from unicellular organisms about four billion years ago, through multicellular evolution from two billion years ago. Human cells are vulnerable to damage, and dead cells are disposed of by macrophages (cells with an “undertaker” function), which decompose and recycle them. This process of necrosis or accidental damage is one of about seven theories of aging. Another is the simple “wear and tear” or mutation accumulation (Goldsmith 2014). Another, known as programmed cell death, or phenoptosis, explains why all organisms must die. Vertebrate embryos display “almost uninterrupted cell growth” (Clark, op cit., p. 29), a pattern that changes, however, for humans as the cells for the evolutionary remnants of gill and web structures, for example, are forced to die at around eight weeks in the womb. Indeed, this has been referred to as “the [programmed] act of suicide by a cell” (Clark, op. cit., p. 32). Cells so affected undergo the process of apoptosis or gradual disintegration.

Clark places the origin of programmed death at one billion years ago, distinguishing between unicellular reproduction by fission and multicellular reproduction by sex. Sexual reproduction has the advantages of genetic variation which enhances

adaptation and of repair and removal of defects. But it is also intimately associated with the “clock of senescence,” as well as the gene-centered view of evolution. Clark here refers to “the irrelevance of our somatic selves” in the universal scheme of things, and here we are faced with the controversy of the scientifically endorsed indifference of nature versus the precious human individuality championed by most religion, social and human sciences, or evolutionary humanism in Chisholm’s (1999) terms.

Disease has always been with us, and human history is partly defined by the terrors and fatalities associated with the black death, syphilis, smallpox, typhus, cholera, tuberculosis, malaria, and others. Dense communities, agriculture, migration, wars and other opportunities have helped diseases to spread. Recent life-threatening epidemics include avian flu, dengue fever, swine fever, AIDS, Ebola, and the Zika virus. Anthrax is but one deadly disease that occurs naturally, can spread among cattle, and can be used as a weapon; in order to preserve its own life cycle, anthrax has no alternative but to kill its human host. Epidemiological research is ever alert to outbreaks; our predators are now rarely visible. The developing field of evolutionary medicine addresses the distal origins of health and disease (Gluckman et al. 2016). In what we might call an ecology of death, monitoring of mortality related to contemporary climate change also shows some positive correlation.

In general, larger animals live longer lives but there are exceptions. Typical maximum lifespan of bats is 2, the mouse 3, canary 24, bear 30, lion 30, gorilla 40–50, chimpanzee 50, elephant 60–80, golden eagle 80, giant tortoise 170, bowhead whale 211. A female Greenland shark has been carbon dated to an age of approximately 400 years, and it is believed the slow-growing species only becomes fertile at an age of 150. Different species of jellyfish live from a few hours to several months, and the unique species *Turritopsisdohrnii* is said to be potentially immortal, at least in laboratory conditions, since it can reverse its aging process. Factors of temperature, calorific intake, metabolic rate, sleep and hibernation, environment, and predatory niche, all

account for differences in longevity. Notable too are those creatures whose deaths are very closely associated with sex: migrating salmon that die after spawning; female spiders that devour their male mates during sex; female toads that drown after breeding events with multiple males (Howard 2016). Many animals use camouflage or displays of false ferocity to deter predators, and some feign death as a strategy for escape (Trivers 2011) as part of a “co-evolutionary struggle between deceiver and deceived” (p.30). Such “thanatomimesis” is sometimes enacted by soldiers on the battlefield in order to deceive enemy combatants and avoid death. As far as we know, humans are rare in their awareness of and emotional responses to the deaths of conspecifics, but some dolphins and whales have been rigorously documented as supporting and carrying their dead young in what appears to resemble mourning behavior (Reggente et al. 2016).

It has been a long-accepted practice to experiment on and dissect animals in order to understand pathological processes. Human cadavers may be dissected to determine cause of death or for medical research. The natural and induced chemistry involved following a death is predictable: coagulation of blood, drop in temperature, rigor mortis, cell death, breakdown of enzymes, putrefaction, the embalming process using formaldehyde, draining of stomach contents, decomposition accompanied by foul odors, dehydration, bloating, and shrinking. Few of us ever witness this process, but Roach (2004) presents an account made palatable by some humor.

Death and Technology

Taylor (2010) argues contentiously that human evolution has long transcended susceptibility to natural selection pressures, by virtue of tool and weapon making, discovery of fire, cooking, the plough, and so on, up until present day sophisticated technology. One way of looking at this unstoppable technological trend is as a *thanatophobic treadmill*, whereby the sense of cognitive and practical mastery of the hazardous environment inflates neural activity (the “runaway brain”), which in turn generates further problem-solving, technology-creating activity. Many of

these discoveries and creations directly enhanced survival odds as well as conviviality, and continue to do so. By and large, we have few natural predators. Our food supply is regulated, indeed for urban dwellers is outsourced to farmers, abattoir workers, and butchers, so that most of us see little death in reality. Similarly, our conflicts against national out-groups are subcontracted to military agents; criminal justice systems where necessary to engage specialist staff to execute murderers; the sick and dying are frequently hospitalized and tended by health and care professionals; and human corpses are transported, embalmed, and disposed of by funeral professionals (Mitford 2000). Of course this pattern does not apply to all cultures, but it is increasingly the dominant trend.

Medical technologies have become very sophisticated, so that perinatal deaths and infant mortality have sharply declined. Many of us experience lifelong medical monitoring, are duly investigated, medicated and treated, and when deemed necessary kept alive on life support machines beyond the point at which we could survive unaided. Dialysis for kidney failure is one of these. Individuals in a coma or persistent vegetative state (PVS) (or “unresponsive wakefulness syndrome”) may be on life support systems for months or years. The PVS is characterized by brain damage rather than brain death, hence the legal and ethical controversies surrounding it. These show the lengths we go to maintain compromised human life, and a charge of institutionalized thanatophobia (i.e., an abnormal fear of death) may be leveled here, but we should remember that the now standard practices of defibrillation and cardiopulmonary resuscitation came into being only in 1899/1947 and 1904, respectively. Medical technology has thereby challenged the parameters of the “irreversibility” of death. Similarly, the lengthy care of those Alzheimer’s patients who lack memory (a major ingredient of personhood) can be seen as challenging another sign of death. In all these ways, independent vitality-compromise or disability is compensated for in a medical-technological war on morbidity which can be read as either compassion-driven or thanatophobic. Alternatively,

it may be read as resentment that creaturely death interrupts our ambitious life projects.

Many of us have minor handicaps such as myopia and hearing difficulties and need artificial aids to function normally, even more so in the case of people with mobility problems and serious health concerns who require prosthetics, painkillers, surgeries, and other medical aids. In a natural (nontechnological) environment, many of us would be unable to survive, that is, we would die. Paradoxically, often our technologies cause accidents, addictions, pollution, and so on, which may in turn cause illnesses, trauma, and sometimes fatal injuries and diseases. Technology is increasingly the human milieu and is inescapable. Most of us now die in unfamiliar settings, usually on acute hospital wards, often uncomfortably and with little control over our own deaths (O'Mahony 2016; Shuland 1997); and grief and bereavement too are forced into an unnatural medical mould (Bandini 2015).

Given internet access, including lifespan calculators, most people have a conscious awareness of their mortality and approximate lifespan prospects. DNA home testing kits are also available which can suggest inherited pathological conditions and genetic risks. Health promotion research and popular dissemination of results affect lifestyle choice and mortality. The actuarial profession uses mathematical models to predict risks of critical diseases and mortality. Lancaster (2009) charts a historical decline in fatal accidents (extrinsic mortality) due to improvements in skillful navigation of the technological environment (see Koopman et al. 2015 for an alternative view), which may mirror the claim of a historical decline in violence, war and their casualties as measured by death rates associated with multiple causes and contexts (Pinker 2011).

Technology does not stop at death, however. Organs of the dead can be transplanted into others' bodies, and some body parts grafted. Beyond the post mortem (and increasingly the digital autopsy), we now have some strenuous research efforts underway to understand senescence and slow it down, so that even if death cannot be defeated it can be significantly

postponed. De Grey (2008) is one of the many gerontologists refusing to accept normal aging and dying parameters. Scientific research on robotics, nanobots, and artificial intelligence also seeks to enhance technologies in the service of slowing senescence, postponing or transcending death in a so-called posthuman future. Thomson (2016) reviews progress in cryonics, the meticulous process of cooling a recently dead body (or, in many cases, only the head) to -196°C and keeping it stored in hypersecure conditions until a future, hopeful scientific breakthrough allows for full resuscitation, and hence a much extended lifespan. Cryopreservation is already used successfully for storing body parts, including stem cells as part of regenerative medical procedures. Posthumous reproduction also throws up many new challenges and possibilities (Brede and Sabanegh 2013).

Cultural and Historical Perspectives

Estimates vary as to the first human awareness of death resulting in the construction of burial sites and rites. Taylor (2003) puts it at 120,000 years ago. This is significant when set against the dating of the first primitive tools at 2.6 million years ago. Val (2016), however, discusses dating uncertainties surrounding the discovery of *Homo naledi's* putative deliberate body disposal in deep caves in South Africa that may indicate a practice of hominid funerary caching (hiding of remains) dating to three million years ago. The earliest Egyptian pyramids and ziggurats were built about 5000 years ago, and Stonehenge and surrounding burial mounds in southern England date to 4500 years ago. A combination of archaeological evidence and speculation suggests that around 4000 years ago in Britain some corpses were laid out for birds to partially devour, the large bones then being buried in a communal barrow. But such deliberate practices are historically marked by fear of souls of the dead and respect, with ample evidence of ceremonial burial dating back to 26,000 years ago. Rivers have also been used for disposal of the dead and still are today in some parts of the world. Taylor's (2003) sweeping archaeological and cultural analysis of death and the practices around it show a multiplicity of

religious and other views, including vampirism, cannibalism, mummification, human sacrifice, and near-death experiences. The archaeologically attested scale of ancient ritual violence and killing in Peru is enormous, where human sacrifice was conducted as part of a belief in communication with supernatural forces.

Some of the earliest literature such as the *Epic of Gilgamesh* (approximately 2100 BCE) portrays encounters with death and quests for immortality. Religion and theology necessarily include prescientific explanations for death, indicating that it has long preoccupied and troubled human beings. Religious and folk psychological beliefs about death dominated until the advent of biology and medicine. We cannot say with certainty that a majority have been afraid of death and averse to discussing it, but there are ample reasons to regard Western civilization today as “thanatophobic,” wary of thinking about and discussing it freely. Attitudes toward death have changed significantly over the centuries (Ariès 1972). Until 1960, the Amazonian Wari’ Indians were known to practice endocannibalism (also known as funerary cannibalism and practiced in other cultures and times), or dismembering, cooking and eating their dead relatives as a mark of respect and affection (Conklin, 2002). The Wari’ have a highly nuanced understanding of death but such practices would be greeted with disgust by Westerners. But consider by contrast, the modern American funeral industry in which death is impersonal, outsourced, and part of the nexus of capitalism (Mitford 2000). Going even further than this, Gunther von Hagens provides an example of the corpses of humans and animals being skinned, preserved, plastinated, and arranged in poses for public exhibition, education, and entertainment.

While many Western funerals have become “clinical,” managed, and minimally emotional, Jinkinson (Jinkinson 2005) reports on death rites in a small Greek island village. Crying and singing may follow the news of death, the corpse is viewed, and the face kissed before burial; after forty days a wake is held; after 5 years the remains are exhumed and the clean white bones are taken, the skull may be kissed; then all is wrapped in linen and stored in an ossuary; this may be

repeated after another year or two to ensure the journey of the dead person is complete. Villagers believe that the dead communicate with the living.

Stearns (2007) reports that in eighteenth century France, older fathers were the most common murder victims, due to sons being unable to gain economic independence while their fathers retained possession of farming land. Within the USA, significant cultural comparisons can also be made (Kunitz 2014). Warner and Swisher (2015) show that adolescent immigrants’ expectations of survival according to race, ethnicity, and nationality (Mexican, Puerto Rican and Cuban) are often characterized by pessimism. Notably, death in the developed world occurs mainly in association with senescence, whereas in the developing world much higher rates of extrinsic mortality are associated with infectious disease, hunger, and dehydration. Mortality rates within developed countries also vary by region, class, and ethnicity, according to several but uncertain factors of nutrition, economics, and life chances. See Rogers and Crimmins (2011) for a comprehensive review.

Religion and Death

The topic of death is found centrally in all religions and it is often claimed that religion, or theistic religion, originated in early humans’ struggle to accept and understand the death of loved ones and the inevitability of their own deaths (see also Varki and Brower 2013). By constructing myths and rituals and embellishing existing narratives, religion evolved to bind groups together to sweeten somewhat the horror of the sight of a corpse, to pacify the imagined deities responsible for death, and to ease the dead on their onward journey to heaven, Valhalla, or paradise. The *Egyptian Book of the Dead*, originating in 1550 BCE, is a funerary text containing spells for assisting the dead on their way to the underworld, or *Duat*.

The monotheistic religions share the theology of the fall, which holds humans responsible for death due to sin: “the wages of sin is death” (Romans 6.23). Humans are “mortals” while gods are immortal. Judaism, Christianity, and Islam depart from each other over the meaning of Jesus Christ but all retain visions of an

afterlife. Christianity distinctively places punitive, sadistic public death at its centre in the crucifixion of its messiah. The claim is made in Christian theology that Jesus raised Lazarus from the dead, was himself riser after being crucified and dying and that his loyal followers would also enjoy physical resurrection. Belief in an afterlife of one kind or another quells fear of death and promises immortality based on keeping the faith or living a good life. Tombstone inscriptions typically include religiospatial metaphors (passed, called away to rest, gone to a better place, “fell out of the sight of men,” and religious hopes (“so he giveth him his sleep,” and “promoted to glory”). The monotheistic tradition also advances various eschatologies, or theories about the expected end times, or annihilation of the entire human species.

Hinduism and Buddhism promulgate a different metaphysics entailing cycles of existence and reincarnation, again closely associated with living virtuously or skillfully. One Hindu group, the Aghoris, worship the deity Shiva, associated with destruction and practice overcoming fear and disgust by frequenting cremation grounds, drinking from skulls, and eating from human corpses. Buddhism is based on the empirical observation that “all life is suffering” and the Buddha’s four noble truths which expound a view that birth, aging, illness and death create suffering, resistance to which reinforces suffering. Afterlife is not the goal, but acceptance without craving a different kind of life: the Buddhist *maranassati sutta*, meditation on death, serves such an end. It is notable that most religious beliefs, including Buddhism, can inspire some followers to risk death in diverse ways, for example undertaking suicide missions (Liddle and Shackelford 2014) or burning oneself to death as a protest against injustice. They can, likewise, sometimes inspire murderous actions against perceived infidels. More routinely, religion provides comfort to the dying and bereaved, and clear practical guidance for disposal of the corpse. A common mystical interpretation of death is that our births are contingent, time is illusory, and the ego that frets about death is also illusory; properly understood in meditation, death cannot

trouble anyone who exists in the pure, animalistic present.

Psychological and specifically evolutionary-psychological analyses of religion are by no means in agreement on this topic, although in principle EP is bound to explain the evolutionary origins of religious behavior: what caused collective beliefs and rituals to arise that were costly in terms of energy output with no discernible immediate payoffs? Theories range across religion as an advantageous adaptation, for example, increasing group bonding against adversity and boosting optimism, spreading like memes or cognitive viruses, or alternatively as being a byproduct of other survival strategies. Although religious belief is often inferred from grave markings up to 100,000 years ago, most formalized religion dates back to only about 4000 years. Interpretations vary enormously and no straight forward, satisfying account has yet emerged. Evolutionary psychology like most contemporary science is skeptical, if not atheistic, and may be inclined to connect decline in religious belief partly with the growth of scientific and technological benefits. Meanwhile, a majority of the world’s population remains religious and holds beliefs in an afterlife.

Gender and Death

Kastenbaum (2000) noted few distinctive gender differences in attitudes toward death, apart from speculatively contrasting the presumed greater emotional openness and communicativeness of women with male machismo and disinclination to show weakness. Some studies suggest gender differences in grief responses and disgust sensitivity, however (Bassett 2015). Causes of death mark some differences by gender, for example, breast cancer and heart disease, and suicide in females more often involves overdose and unsuccessful outcomes, contrasted with more violent methods such as shooting and hanging used successfully by males. Women have tended to live longer lives than men by a margin of a few years, which appears to contradict evolutionary assumptions that sexual fecundity is the key to individual survival. In the European Union in 2014, for example, women in the Netherlands outlived men by 3.5 years, and in Lithuania by

10.9 years. In almost all species, females outlive males, with, for example, adolescent male macaques often dying much younger and female sperm whales sometimes living longer by as much as 30 years. It is inferred that African male lions have higher mortality rates than females, whether due to being hunted or for other reasons.

Menopause normally spells the end of female reproductive usefulness, whereas men remain fertile into old age. It is speculated that various factors point to menopause being protective for women, especially in connection with fecundity at relatively advanced ages. Menopause may also underlie investment in grandmothers' childcare based on the lengthy development of human offspring. Additionally, estrogen has beneficial health effects. By contrast, testosterone is associated with high rates of death due to risk-taking (reckless driving, violence, etc.) in the 15–24-year-old age group (Wilson and Daly 1985) and in midlife due to suicide, alcohol consumption, and heart disease, as well as having immunosuppressive effects (Bribiescas 2016). While males tend to be taller, stronger, heavier, and faster, women's slower metabolism may protect them better from fatal diseases. Kruger and Nesse (2004) conducted a detailed analysis of mortality by gender, age, and cause of death across several countries which confirms the sexual selection thesis favoring female longevity. Contrarily, from a feminist perspective, Kruger, Fisher, and Wright (Kruger et al. 2014) predict that greater social equality leads to decreased male mortality and hence a narrower gap in the traditional male and female mortality ratio.

Philosophy of Death

Socrates asserted that all philosophy is preparation for death but the best-known “philosopher of death” may be Epicurus. It is here that analysis of fear of death finds its most cogent Western expression. Epicurus's famous reasoning was that while we exist, our death does not exist, and where death exists we are nonexistent. In neither case are we co-existent with death and we therefore need not fear it. Epicurus and his followers did not regard the idea of any form of posthumous survival as compatible with embodied life and continuous

memories which constitute human being. To some extent, this kind of logic is found in present day espousers of “amortality,” and cognitive behavioral psychotherapy that addresses death anxiety clinically (Furer and Walker 2008). Others including Nagel (1970) have disputed this reasoning, arguing instead that death, our annihilation, deprives us of the goods of life. Examples of highly creative but relatively short-lived people are used to illustrate this claim.

Bradley, Feldman, and Johansson (Bradley et al. 2013) demonstrate the sheer number and complexity of philosophical questions stimulated by death. These include specificity of time of death; loss of personality; the nature of the corpse; survival of death; immortality; emotion and rationality; the wrongness of killing; abortion; war; capital punishment; and animal death among others. These lie in the analytic and ethical tradition, but one of the best known continental “philosophers of death” is Heidegger, whose existentialism focuses on the authentic requirement to factor death into one's daily awareness. It is one's own death that counts, we do not know when we will die but it could be at any moment, we die alone, our lives are “being toward death,” and it is our attitude to death, not physical demise, that is important – these are some core Heideggerian principles.

One branch of moral philosophy that is both uncomfortable in its own right and potentially fruitful for evolutionary psychology is summarized by Broome (2004) in his highly technical book *Weighing Lives*. This confronts us with comparing good with arguably less good lives, and with cases like terminal illness where decisions must be made between palliative care and aggressive medical intervention. Drawn to considerations of longevity, we may easily ignore the contrasts between the qualities of lives (Small 2010). However, even today, it is unlikely that the majority of people employ careful analytic methods for addressing such problems; rather, evolved, rapid computational (heuristic) affect and compromise guide most such judgments and actions. Suicidal ideation, for example, may be construed in philosophical terms, or psychoanalytically, or even parasitologically, say, but an EP

analysis may explain it in terms of altruism to increase inclusive fitness for kin or as a byproduct of malfunctioning evolved mechanisms (Aubin et al. 2013). Another interesting philosophical challenge comes from a bioethical stance which refuses to accept normative “bravery” in the face of life-threatening illness, instead recognizing the reality of “antiheroic” experiences (Diedrich 2005).

Criminology and Death

Crimes involving death most obviously center on murder but there are many categories of killing, from a one-off crime of passion or drug-related felony, through killings by organized crime syndicates to serial murders with sexual motivations or associated with mental illness, mass killings in the name of terrorism, and necrophilia. Killing is taboo in almost every society, and an examination of death must ask what motivates inflicting death on others and risking harsh social sanctions. Buss (2005) presents evidence that although 87% of murders are committed by men, fantasies of killing others have been experienced by 91% of men and 84% of women. Buss argues on the basis of many interviews that the capacity to kill in certain circumstances is rooted in our nature, specifically associated with reproductive competition. Rather differently, Thornhill and Fincher (2011) apply parasite stress theory and collectivist identity to cases of homicide. Some writers have argued that human nature retains a cannibalistic capacity, and indeed this is observed in some extreme survival scenarios.

Necrophilia is the act of sex with a corpse. Widely treated as a crime and psychiatric disorder, necrophilia can entail motives of attraction to corpses, power, enjoyment of sex without rejection, and reunion with a deceased lover. It is of particular interest because, unlike “simple” murder which is taboo, necrophilia also overcomes the common taboo against disrespect and disgust with corpses. Serial killers well-known for necrophilia, such as Jeffrey Dahmer, Dennis Nilsen, and Ted Bundy, are not necessarily the typical culprits, however, since opportunistic necrophilia is documented among some partners of the dead and individuals who work in the death industries.

Incidence of necrophilia is unknown but assumed to be rare and is unlike the examples of homicidal fantasy given by Buss (2005). Since sexual coitus with the dead has been observed historically and transculturally, and in a variety of animals (including ducks, doves, penguins, and sea lions), it may be inferred to be a relatively uncommon but cross-species phenomenon (Finbow 2014).

Acts of killing in self-defense, killing (and dying) in the line of duty (police, military personnel), and mass killings in war are not usually regarded with the same sense of taboo or disgust. War *crimes*, however, are defined differently, which leads to questions about justifying killing in the name of one espoused ethics while demonizing those in the ethical out-group. Close encounters with sudden death often lead to post-traumatic stress disorder, given the relatively rare experience of witnessing horrific, disgusting fatalities that can create chronic shock (Engelhard et al. 2011).

Psychology of Death

Little specific literature existed prior to the 1970s on the psychology of death, unless we include works such as Freud’s (1917/1957) *Mourning and Melancholia* in that genre, Lindeman’s (Lindemann 1944) focus on the time taken to process acute grief and Kubler-Ross’s (1969) stages of grief model. Kastenbaum (2000) remains a key resource, which begins with the child’s progressive understanding of death. He points out the significant differences between observing a hamster die (“it is dead”) and internalizing the lesson that “I will die.” The child learns about absence, abandonment, separation, and nonresponsiveness in connection with death, but the sense of time develops slowly. Indeed, across the lifespan, the sense of time and distance from death develops quite slowly.

Early exposure to others’ deaths impresses on children features of coldness, immobility, and nonresponsiveness, and memories of death often focus on “thanatic fetishism” or small details (Hall 1922). As Kastenbaum (2000) speculates, parallels between sex and death can be inferred here, recalling psychoanalytic interpretations; some

have also speculated on connections between sex, death, taboo, and pornography. The expression *la petite mort* (little death), corresponding with orgasmic surrender, connotes brief loss of consciousness and, like sleep, depicts us at our most defenseless in these domains; sleep is also a common metaphor for death. We should perhaps not be surprised at the “polymorphous perversity” of cultural and individual ideas and practices about death. We might also infer a parallel between the child’s formation of memories, emotions, and ideas about death, and those of primitive humans first exposed to the sudden death of others, and human corpses, perhaps experiencing some of what we now call post-traumatic stress disorder (PTSD), and able to vividly understand their own mortality, and to unconsciously deny it (Varki and Brower 2013).

It may be that the neurology and psychology of PTSD, obsessive compulsive disorder, and some phobias hold important clues to the evolution of chronic death anxiety. These conditions recall or anticipate vivid life-threatening events and appear to be rooted in an ancestral environment in which sudden death followed bites by spiders and snakes, falls, eating toxic foods, or deadly encounters with animals or other humans, bequeathing hardwired states of defensive hyper vigilance, avoidance, and ritual compulsions. Close associations are also seen between conspecific deaths, mourning, and depression. The developing field of evolutionary psychiatry captures such phenomena (Brune 2015) and the evolutionarily ancient amygdala is often implicated.

Kastenbaum (2000) discusses the “mature view of death,” which rests on acceptance of mortality as universal, personal, inevitable, and irreversible. This emphasis on logic and de-emphasis of belief is disputed by many with different cultural and religious views of death and returns us to the question of denial. Other “extreme” refusals of the mature view, however, include death anxiety and calculated or impulsive risk-taking in the face of death. Death anxiety is pervasive in life and in the literature on death, and attitudes toward death are well summarized by Neimeyer, Wittkowski, and Moser (Neimeyer et al. 2004).

Kubler-Ross (1969) initiated one of the first and best-known models of stages of grief which applies to grieving relatives but also to other loss situations including a terminal diagnosis. The stages are denial, anger, bargaining, depression, and acceptance. While aspects of the model can be readily accepted, it is referred to as a myth by many since empirical evidence is lacking as to any linear “journey” across the five stages. Nevertheless, it remains influential in popular terms. Acute grief triggered by another’s suicide can also lead to so-called copycat, cluster or contagion suicides, and some natural deaths too apparently trigger heartbreak intense enough to lead to associated partner death. Potential behavioral contagion of this kind is sometimes given as a reason to prohibit euthanasia. Suicide prevention initiatives by psychiatry, legal systems, and voluntary organizations in mass populations require explanation beyond mere thanatophobic hysteria or uncritical pro-life assumptions, which may lie in the psychology of voodoo or nocebo effects.

Another, mainly discredited theory is Freud’s death drive, or instinct, which purports to show that humans are driven not only by *eros* but by an urge towards aggression, death, and self-destruction. The finding that a 13.8% chance of day of death coinciding with date of birth, proposed as an “anniversary reaction” (Ajdacic et al. 2012), might support Freudian theory. Yet at the same time, Freud had argued that the unconscious cannot imagine its own death. Certain psychotherapies utilize such life-and-death themes conceptually and clinically. Weatherill (1998), Razinsky (2014), and others have built further on Freudian psychoanalytic principles, and some theorists retain a psychosomatic etiology linking mind, illness, and mortality. A stoical-existentialist view can be found, while Furer and Walker (2008) commend cognitive behavior therapy. Kellehear (2014) is a relatively rare account of the dying person’s own experience, which includes some uplifting material.

Terror management theory (TMT) places death, or mortality salience, at the heart of psychology, offers a rival explanation to EP for human motivation and behavior, and ongoing tension exists between TMT and EP. Becker (1973)

speculated, drawing on the work of philosophers and psychologists among others, that fear of death drives all human endeavors, with humans behaving heroically to deny the fact. This led eventually to TMT, which is now supported by a wide range of situational applications and associated empirical research (Greenberg et al. 2004; Burke et al. 2010; Solomon et al. 2015; Harvell and NIsbett 2016). Buffers against the terror induced by thoughts of one's own mortality include self-esteem, religion, worldviews, different attitudes to health, and other defensive behaviors.

Navarrete and Fessler (2005) argue that TMT is incompatible with evolutionary biology, that mortality salience is not the all-powerful force it is deemed to be, and that coalitional psychology offers a better explanation for defense of in-group ideologies than TMT. They argue that although a fear and avoidance of predators exists, no fear of "death as such" exists. Humans have no generic 'survival instinct' but an emphasis on reproduction along with cognitive modules for addressing specific threat situations in the environment. Landau et al. (2007), however, appealed for compatibility. Tritt et al. (2012) suggest that TMT "runs counter to prevailing views in neuroscience" (p. 721) and offer a biological understanding of mortality where "death is not so special" (p. 728) but simply another instance of an uncertainty to be resolved by an ancient brain-based anxiety system. Kirko (2016) argues that unconscious death awareness is a better explanation than conscious death anxiety, which would be a more costly defense. This might go some way toward harmonizing TMT, EP, and related theories of mortality salience (Varki and Brower 2013). For Varki and Brower, however, mortality salience and its appearance in human evolution is more than a large and troublesome motivational force: realization of the meaning of personal death and the self-deception required to live with it, in order not to succumb to perilously morbid preoccupation, is here the explanation for the emergence of distinctive human consciousness itself.

Evolutionary Psychology of Death

Death is often treated tacitly in the literature of evolutionary psychology, for example, as the

ultimate cost of failure to adapt or simply the end point of evolved senescence. Darwin (1859/1968) in his epochal *The Origin of Species* barely mentions death. Rather, he speaks of how "Natural Selection almost inevitably causes much Extinction of the less improved forms of life" (p. 68). "Each organic being . . . has to struggle for life, and to suffer great destruction" (p. 129). "Unless we believe that the number of specific forms goes on perpetually and almost indefinitely increasing, numbers inevitably must become extinct" (p. 153). Darwin's focus here was on species death, and we now know that the vast majority of species that have ever existed have gone extinct (and not usually in dramatic extinction events), with the rate of anthropogenic extinction today accelerating. But we can infer from this that so far all discrete life forms, ourselves included, are destined to perish.

The publication of Dawkins' (1976) *The Selfish Gene* also lacked significant attention to death. However, Dawkins speculated that senescence may result from "deleterious copying errors and other kinds of gene damage" (p. 42). He also builds a little on Medawar's (1952) work to suggest that "lethal genes" and "semi-lethal genes" that are late-acting survive because they do not interfere with sexual reproduction earlier in life. Williams (1957) postulated about senescence that in terms of survivorship among early humans about half of infants came to sexual maturity: late life fitness had no value for natural selection. Peak fertility from around puberty is most valued by natural selection. Senescence is a "steady decline in adaptive performance" (op.cit., p. 172), resulting from antagonistic pleiotropy, whereby genetic processes trade-off early fertility for later morbidity. Natural selection does not produce perfection but pragmatic functional adaptations. While much controversy and uncertainty exist in this area, Wolpert (2009) is unequivocal: "The blame must fall on evolution, which is interested only in reproduction and not in health once we have reproduced" (p. 146). A contrary view is put by Shostak (2006), who argues that our technologically extended and lifestyle-extended existence is boosting juvenile features which via evolutionary forces acting on cellular activity is lengthening the

lifespan and delaying death. Werfel et al. (2015), using stochastic modeling, argue that limited spatiotemporal resources favor shorter, not longer, life spans, and hence that classic evolutionary theories of senescence are insufficient.

Suicide presents an acute challenge to evolutionary psychology if killing oneself is naively regarded as contrary to a “survival instinct.” However, sexual reproduction and successful care of the young, and not survival *per se*, are the evolutionary objective (DeCatanzaro 1991). Early life suicides can be seen as removal of an unfit individual from the gene pool. Altruistic suicides may include putting others first in order to prioritize scarce resources or removing oneself if a burden on others. Nevertheless, few other animals are known to commit suicide on the scale of humans (Ramsden 2010), and we may have to conclude that some humans experience distress so acute or chronic, accompanied by the cognitive expectation that no relief is forthcoming, that suicide seems the only solution. To say that someone “died by his own hand” also underlines evolved, distinctive human dexterity. Technology usually facilitates it, with pills, poisons, hanging, guns, knives, railway tracks, and tall buildings all available.

Similar to suicide, filicide superficially appears to have no adaptive value if passing on genes is the “purpose” of life. Infanticide by step-parents or others, however, may sometimes show a brutal genetic logic. Indeed, in the Paleolithic era, it is estimated that up to 50% of female infants may have been killed and significant infanticide to offset scarcity of resources may have continued until the Neolithic Revolution and the advent of agriculture (Milner 2000). Religious sacrifice of children also had a logic for its time. Infant mortality in eighteenth century France was so high that streets were “littered with the corpses of dogs and babies during famine periods” just prior to the demographic transition in which mortality and fertility both started to decrease in the developed world (Barret et al. 2002, p. 159). Even today in some cultures, infanticide is practiced, with more girls than boys being killed or abandoned. Volk and Atkinson (2008) argue for a better evolutionary understanding of the problems of child mortality, particularly the costly failure of gene transmission.

So-called social Darwinism is bitterly attacked for propounding views derived from Spencer and Galton placing emphasis on the “survival of the fittest” and “rational selection.” In this account, natural selection is replaced by the decisions of human planners and eugenic technologies. Darwinism was expropriated by Nazism and racial science to justify genocide on the grounds of eliminating human specimens and groups perceived as weak or degenerative from the gene pool. This was to ignore entirely human rights, the benefits of co-operation and the perils of pseudoscience. Nevertheless, EP is bound to have to address matters of the mass psychology of contemporary xenophobia and genocide (Smith 2012). Similarly, Malthusianism, framing death as an unfortunate “positive check” on continuing population growth in relation to limited resources, invites ongoing political controversy.

Life history theory (LHT) links genetic variation and mortality with scarcity of resources and an evolutionary underpinning. Based on cross-species mathematical analyses of the age schedule of birth, maturity, size, timing of reproduction, number of offspring, senescence and death, and environmental uncertainty, LHT embraces the notions of slow and fast life histories corresponding with life expectancy, not only in humans but mammals generally (Dobson and Oli 2007). Some studies of dates of death (e.g., Ajdacic et al. 2012) and evolutionarily driven circadian rhythms affecting time of death (Lim et al. 2012) are also suggestive here. In the case of contemporary calculations based on socioeconomic status, some individuals over-estimate the likelihood of premature death (“you have to live for the day”) and engage in high-risk activities with self-fulfilling properties (Griskevicius et al. 2011). Another area of potential for EP is provided by Gorban et al. (2016) who draw on Selye’s stress model to develop an evolutionary, hypothetical “adaptation energy” model of fitness optimization supported by mathematical work.

Evolutionary mismatch theory helps to explain some of the diseases of modernity, including breast cancer, obesity, and diabetes. Human longevity has been increasing, most lives are no longer nasty, brutish, and short, indeed we face new diseases of old age. In addition, psychosocial

factors such as loneliness, particularly in the developed, secular world, account for some increase in premature deaths (Holt-Lunstad et al. 2015). It may be important to consider evolutionarily recent and contemporary population and behavioral genetics, and increasing resistance to some diseases (Cochran and Harpending 2010). Simultaneously, with greater public acceptance of Darwinism and challenges to religious denial of mortality, more people are faced with the problem of finding strategies for sustaining morale. Growth in antinatalist awareness, for example, alongside various catastrophe scenarios, makes for demoralization, while improvements in health care, increasing longevity, and advances in technology make for hope (Chisholm 1999). An evolutionary psychology trained on more recent adaptations might well make useful predictions regarding this latter challenge.

Conclusion

Death is inevitable and necessary even if the lifespan may be stretched: to be born is to die (Shields 2008), or “life, thus death” (Volk 2002). Humans are aware that they must individually die, whether “prematurely” or by senescence, but this universal fact of life remains an unpleasant prospect, often feared and minimized in conscious common discourse. Science, however, continues to make unsettling discoveries such as Chen et al. (2016) which, taking over 13,000 individuals from three ethnic groups, finds that “epigenetic age” predicts death better than chronological age, lifestyle, and common risk factors. Human evolution and culture have brought about momentous changes distinguishing the human from the animal world, notably advance awareness and religious denial of personal annihilation, technology that extends life, and some degree of apparent free will. While it is true that we share some vulnerabilities with wild animals, we have escaped much of the “nature, red in tooth and claw” aspects. At any given time, “thousands of animals are being eaten alive, others are running for their lives, whimpering with fear; others are being slowly devoured from within by rasping parasites; thousands of

all kinds are dying of starvation, thirst and disease” (Dawkins 1995, p.154).

Responses to human mortality are culturally, historically, and disciplinarily highly pluralistic. The domain specificity of EP addresses important human functions of social and sexual interaction but does not accord mortality a particular place in its canon, as TMT does; it looks instead at aspects of life history theory, senescence, mismatch and trade-off theories of disease causation, disgust sensitivity, and sexual selection for fitness. The enormous energy costs demonstrated throughout human history, of propitiating the gods, denying, and postponing death, however, heavily imply a collective need to address mortality, an onus on academics to engage in an interdisciplinary focus, and a nuanced explication of the proximal-distal discrepancies in accounts of contemporary life and death.

Death by Suicide

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

Completed suicide; Self-annihilation; Self-destruction; Self-murder; Suicidal enactment; Suicidality; Suicide

Definition

Suicide constitutes the intentional act that is actively causing one's own self-destruction.

Introduction

Death by suicide is the voluntary and explicitly deliberate engagement of an individual in a series of operational, external, as well as internal activities that result in her/his death. Suicide is a complex, multifaceted, and multifactorial phenomenon, and, while it is considered a global epidemic, it is a preventable cause of death (WHO 2014). Specifically, the suicidology literature has consistently indicated that high levels of suicide risk are frequently short term and are triggered by a specific stressful situation. Although suicidal ideation might reappear, it is not a permanent symptomatic condition, and the formerly affected person, given multidimensional support (medical, psychological, social), can live a long-lasting and meaningful life (Torres 2016). Additionally, while there are incidents of suicide that manifest without warning signals, most of the cases of completed suicide have been preceded by idiosyncratic warning signs (e.g., cognitive, emotional,

or behavioral). Therefore, identifying the warning signals which indicate that a person is experiencing a suicidal crisis could help the individual receive appropriate early treatment, which in turn could increase her/his possibility of surviving the suicidal crisis (Sadek 2019).

According to the World Health Organization (2014), suicide is considered to be the tenth leading cause of death across the globe and the second leading cause of death in the age group 14–29 years old. Nearly 750,000 individuals die by suicide annually, and it is estimated that in 2020 deaths by suicide will significantly increase across the globe to nearly 1.5 million per annum (WHO 2014). Moreover, it has been consistently indicated that approximately 10% of the general population has a history of a suicide attempt. That is, for every person who died by suicide, multiple individuals have attempted to take away their own lives each year with incidents of suicide attempts being approximately 25% higher compared to the incidents of completed suicide (Torres 2016).

Furthermore, it has been observed that suicide is a global phenomenon (Sadek 2019). However, it is widely cited that it manifests in significantly higher rates in low-income as well as in middle-income countries. In particular, 79% of deaths by suicide that occur globally usually manifest in countries with low- and middle-income economies. Generally, the sociopolitical geographical area of Eastern Europe exhibits the highest overall levels of suicide. The Central and South American geographical regions, as well as the countries of the Mediterranean, manifest the lowest levels and the United States, the west European countries, the Asian countries, and Africa somewhere in between (WHO 2014). Nonetheless, there is a significantly high variation among sociopolitical geographical areas concerning reporting incidents of suicide (Torres 2016).

The Multifaceted and Heterogenous Phenomenon of Death by Suicide

Suicide constitutes a multidimensional outcome. Specifically, there is a wide range of cultural, sociological, psychological, physiological,

genetic, and psychiatric factors that can contribute to the manifestation of death by suicide either independently or in interaction with one another. Thus, suicide is a complex phenomenon, with every incident reflecting an idiosyncratic mixture that consists of a dynamic interplay between qualitatively distinct contributors (Pompili 2018).

Additionally, the most widely accepted motivational factor of suicide in the clinical literature is considered to be the long-term frustration of psychological needs (e.g., sense of safety, autonomy, secure attachment system, belongingness, and self-efficiency and sense of purpose, control, orientation, and meaning in life). Specifically, the driving force of most suicides is the long-term frustration of an idiosyncratic mixture of basic psychological needs that are necessary for a healthy, meaningful life (Torres 2016). Therefore, clinical interventions that aim to help people cultivate and solidify their capacity to nourish and, thus, adequately satisfy their psychological needs could prevent suicide. Over and above that, most suicidal individuals who have the opportunity to safely explore their experience with an empathetic other are ultimately able to contain their emotions, feel interpersonally supported, and attain a viable degree of psychic equilibrium (Maris 2019). This often can lead them to reconsider their decision to commit suicide. Therefore, the availability of emotional support has the potential to prevent suicide.

However, due to the stigmatization that revolves around suicidal crises, individuals who are affected often do not feel safe to express their thoughts and feelings to their significant others and even seek professional help (Wasserman and Wasserman 2009). Stigmatization related to suicidal experiences inhibits suicidal recovery. Specifically, it has been consistently found that encouraging suicidal individuals to openly talk as well as freely explore their experience could provide them the opportunity for emotional containment, problem-solving, and decision-making something that, in turn, might enable them to reconsider their choice (Maris 2019). This is in contrast with the misconception that encouraging talking about suicide could reinforce the person's intention to commit suicide (Torres 2016).

Risk and Protective Factors

The clinical literature has consistently shown that there is a significant association between previous suicide attempts and completed suicide in the future. Nearly 45% of people who had attempted to take their own lives ultimately die by suicide. Therefore, a history of suicide attempts represents one of the major risk factors for death by suicide (Maris 2019). Furthermore, a substantial amount of research has found a significant association between mental disorders and suicidality (Karthick and Barwa 2017). Specifically, clinical depression, substance abuse and related disorders, trauma- and stress-related disorders, psychotic disorders, eating disorders, and conduct disorders have been consistently associated with a higher risk for death by suicide (Hirsch et al. 2019). However, while psychiatric disorders constitute significant contributors associated with suicide, neither all individuals who have a mental illness experience a suicidal crisis nor all people who die by suicide met the criteria of a psychiatric disorder (Lennon 2019). Thus, psychiatric disorders alone cannot explain the factors that contribute to the manifestation of suicide.

Furthermore, a family history of suicide has been consistently found to increase the risk of suicide. This implies that there is a genetic predisposition that contributes to the manifestation of suicide (Maris 2019). Moreover, knowledge and access to lethal means significantly increase the risk of suicide. Additionally, gender seems to be a significant risk factor, with females exhibiting higher rates of suicide attempts and males higher rates of fatal suicide attempts (WHO 2014). Further risk factors that are significantly associated with suicidality include unemployment and age, as older people exhibit significantly higher rates of suicidal behaviors. Moreover, the clinical literature has consistently found significantly higher rates of suicidal behaviors in people that exhibit chronic pain and functional deficits (Wasserman and Wasserman 2009).

Additionally, research related to suicidality has designated various protective factors regarding suicide. Specifically, some of the most cited protective factors for suicidality include education,

employment, access to medical care services, secure attachment system, marital status, social and communal integration, self-efficacy, emotion regulation, gratitude, hopefulness, cognitive flexibility, sense of purpose, orientation and meaning in life, and problem-solving and decision-making skills (Maris 2019).

The Suicidal States of Mind

A suicidal crisis is governed by profound psychic pain, which is characterized by floods of intolerable affect. Additionally, the main objective of suicide is to find a solution that would free people from the emotional drama, dilemma, as well as a life crisis that they might be experiencing. In other words, people who contemplate suicide think that death is the only feasible solution at their disposal that will ensure the end of their suffering (Pompili 2018). Furthermore, suicidal individuals often report that they experience a sense of entrapment and aloneness in a state where they feel defective and hopeless. This dynamic often triggers despair, rage, self-hatred, and existential anguish that involves disintegration anxiety and a powerful urge for immediate relief (Barzilay and Cohen 2017).

Moreover, one of the major qualitative functions of contemplating suicide is to alleviate the unbearable psychophysiological distress. Notably, during the experiential process of fantasizing and organizing suicide, the affected individuals feel that they have restored some of their sense of power and control over their suffering. That is, they feel that they can actively stop their ongoing suffering, which in turn decreases to some extent their sense of entrapment, hopelessness, and uselessness (Barzilay and Cohen 2017).

Additionally, when suicidal individuals feel imprisoned in an internal and/or external condition where they experience hopelessly intolerable psychophysiological pain, they are usually reacting with rage of high intensity (Maltsberger et al. 2018). In some cases of completed suicide, this reactive rage of being helpless constitutes the driving force that enables people to overcome the fear that is being activated by their survival and

reproductive instincts and thus proceed to kill themselves. Consequently, the suicidal states of mind are significantly associated with the affected individuals' inability to function adaptively in times of intolerable distress (Kapur and Goldney 2019).

A core characteristic of the phenomenological experience of suicidality is the quality of ambivalence (Maris 2019). That is, people who are contemplating suicide are also experiencing an inherent intrapsychic conflictual dynamic. Specifically, there is an intrinsic conflict between their instinct for survival as well as reproduction and their belief that indicates to them that the only feasible solution for escaping their psychophysiological pain is self-destruction (Barzilay and Cohen 2017).

Moreover, most people who experience a suicidal crisis exhibit a transient perceptual constriction, which prevents them from recalling the internal representations of themselves, others, and the world that could enable them to mentalize, and thus make sense of their experience (Sharma and Fowler 2018). Moreover, suicidal individuals experience difficulties in accessing their problem-solving and decision-making abilities effectively (Maris 2019). These deficiencies usually lead the affected individuals to rely on dichotomous cognitive-affective functioning (e.g., black/or white emotions and thoughts) as they experience a perceptual splitting between the past, the present, and the future. Consequently, they often feel trapped in the present moment of their suffering, which reinforces their suicidal ideation (Maltsberger et al. 2018). Moreover, people who experience a suicidal crisis exhibit a deterioration of their ability to recall autobiographical memories. This diminishes considerably their capacity for positive future thinking, which is one of the major capacities which facilitates the formation of positively oriented experiences (Hirsch et al. 2019).

Trauma and Death by Suicide

Mental trauma usually results when people experience intolerable levels of psychophysiological

arousal, which transcends their ability to endure and integrate their sensory, affective, and perceptual experience into symbolic representations that could have enabled them to contain their emotions and make sense of their experience (Maltsberger et al. 2018). However, the ability to endure externally as well as internally distressing conditions is the result of a dynamic interplay between genetic, psychological, and environmental factors and varies among individuals. Additionally, there is generally a consensus that the distressing stimuli which can trigger a traumatic experience can either be external (e.g., environmental) or internal (e.g., neuropsychological states, traumatic affects) (Maris 2019).

The cardinal feature that governs traumatic experiences is the inadequacy of the mind to process, regulate, and adapt to mental disequilibrium that is triggered by an external and/or internal stimulation. This stressful dynamic between the inner and the outer world often leads to a sense of entrapment and feelings of helplessness and hopelessness (Maris 2019). Also, there is a substantial amount of research studies that indicate that suicidal crises sometimes reflect the internal re-experience (e.g., flashback) of overwhelming neurophysiological distress, which was initially experienced in past traumatic events (Wasserman and Wasserman 2009).

Additionally, persistent and repeated suicidal crises might have long-term re-traumatizing effects. It should be pointed out that suicide attempt survivors are considered survivors of attempted murder as they are the perpetrator and the victim at the same time. Therefore, the suicidal act has the quality of a violent and potentially lethal assault (Maltsberger et al. 2018). Furthermore, recurrent and persistent traumatic experiences that trigger unbearable psychological pain disrupt the capacity to form and maintain secure attachments, something that often leads to the deterioration of ones' ability for hopefulness during life crises. This adverse type of mental trauma might also severely disrupt the affected individuals' capacity of distress tolerance during stressful times in the future. Specifically, recurrent and/or persistent mental traumas have been significantly associated with increased levels of

anhedonia, despair, existential, and disintegration anxiety. This implies that people who experience recurrent and persistent traumatic experiences find it challenging to hold on to hope and maintain their attachment bonds, which have essential life-preservative qualities (Pompili 2018).

Furthermore, the clinical literature has consistently found a significant association between childhood mental trauma (e.g., neglect, sexual, physical, and psychological abuse) and post-traumatic stress disorder as well as increased suicide risk in adolescents (Kapur and Goldney 2019). Moreover, there is a substantial amount of research that indicates that traumatic experiences influence the phenotypic expression of the operational mechanism of emotional self-regulation during childhood (Fonagy et al. 2002).

In addition, traumatic mental experiences can disturb essential operational properties of explicit memory and perception (Maris 2019). That is, following a traumatic experience, a functional somatosensory organization (e.g., outside of the symbolic realm) of the traumatic experience is immediately formed, which is, to a great extent, rigid and resistant to modification. Intolerable affective states lead to traumatic experience because they interfere with the process of assimilating the experience into existing mental schemas. Precisely, intolerable affective states lead to the dissociation of perceptions and memories of specific events which in turn are stored as visceral, visual, and olfactory sensations (Maltzberger et al. 2018). As a consequence, affected people tend to experience fear that has the quality of an unexpected assault in reaction to all the stimuli that have been somatosensory organized due to their association with the arousal-related bodily sensations. Thus, their perceptual lens predisposes them to be in a state of constant alertness waiting helplessly, an assault that would make them suffer. This dynamic elicits cognitive confusion and a sense of being entrapped and hopeless that is increasing the risk for suicide (Pompili 2018).

Moreover, suicidal people who have experienced attachment trauma during their early years of life do not sufficiently develop the capacity for self-object constancy (e.g., capacity to perceive the self and others as whole and constant)

(Maltzberger et al. 2018). Insufficient capacity for self-object constancy makes it extremely difficult for them to retrieve their internal representations of themselves in relation to the nurturing and soothing people that are currently in their lives (e.g., attachment bonds) in times of distress and thus be able to elicit the sense of their presence when they are physically absent (Sloate 2016). Consequently, even minor interactional conflicts often lead them to feel that they have been abandoned, misunderstood, and maltreated. The sense of abandonment and maltreatment increases their suicide risk as it gives rise to extremely intense feelings of dependency, rage, despair, worthlessness, alienation, aloneness, hopelessness, and helplessness that have their roots in their traumatic experience during their early childhood (Maltzberger et al. 2018).

On the contrary, there is a general consensus within the developmental psychology field that people whose parents were good enough during their early stages of development are more likely to develop and maintain the life-preservative capacities for basic trust, autonomy, interconnectedness, emotion regulation, self-compassion, and hopefulness that are negatively associated with post-traumatic stress disorder and risk for suicide (Allen 2013). This is to some extent due to an identification with stable, resilient, empathetically attuned, and nurturing parental models. That is, the identification with good enough parents enables children to subsequently internalize the capacities that their parents exhibit in order to provide for them a good enough environment in which they can survive, grow, reproduce, and flourish. Therefore, good enough parenting can facilitate the expression of constitutional resilience and the internalization of life-preservative capacities and, thus, lower the risk for mental trauma and death by suicide (Barzilay and Cohen 2017).

Theoretical Conceptualizations of Death by Suicide

Mentalization-Based Therapy

Humans rely to a high extent on relational attachments to survive, grow, reproduce, and

find meaning in life (Allen 2013). Mentalization is a functional construct that enables humans to make use in an integrate way their perceptual, inferential, and imaginative capacities in order to reflect on and comprehend the qualitative operations that influence peoples' idiosyncratic mental functioning (e.g., belief system, incentives, feelings) (Sharma and Fowler 2018). The ability to mentalize is crucial in the formation and maintenance of the operational mechanisms that render people capable of adaptive functioning in their everyday lives. Moreover, there is a substantial amount of research studies that indicates that the ability to mentalize is of vital significance in the development and maintenance of stable and mutually beneficial relationships (Fonagy et al. 2002).

Furthermore, it has been consistently cited that there is a significant association between suicidality and a dysfunctional family system of origin that do not sufficiently meet the neurodevelopmental needs of the affected person (Allen 2013). Additionally, it has been consistently found that a dysfunctional family of origin is associated with insecure attachment systems and a disordered ability for mentalization and emotion regulation (Sharma and Fowler 2018). This is in accordance with data indicating that people with an insecure attachment system and a disordered ability for mentalization find it very difficult to rely on the people that surround them in times of distress. This can lead them to experience aloneness, which in turn can trigger feelings of despair and terror that increase their risk of suicide (Maltsberger et al. 2018).

Over and above that, people who fall into a suicidal crisis manifest a series of common alexithymic features such as externally oriented cognitive functioning, low emotional intelligence, and constricted imagination (Lester 1991). That is, most suicidal individuals exhibit difficulties in recognizing and distinguishing their emotional states from their neurophysiological sensations and the neurovegetative symptoms that they exhibit during times of stress. Specifically, their capacity to symbolize affects and neuropsychological sensations is significantly diminished, and thus, they do not adequately regulate, explore, and express their subjective experience.

Consequently, their cognitive-affective lens through which they regulate their internal and external experiences is shaped mostly by external stimuli (Allen 2013).

Moreover, people who exhibit a disordered capacity for mentalization and emotion regulation often try to contain their emotional experiences through the psychophysiological mechanism of somatization and thus acting it out. Hence, conflictual relational dynamics usually lead to the manifestation of quick and intense shifts in their emotional state of mind, which is, in turn, manifested in the form of neurophysiological disequilibrium. This neurophysiological disequilibrium is often regulated through self-injury and suicidal preoccupation (Sharma and Fowler 2018).

In addition, mentalization-based therapy (MBT) has been found to significantly decrease the risk of suicide in adolescent and adult population (Sharma and Fowler 2018). MBT for suicidal individuals is designed in such a way as to cultivate a therapeutic environment in which the focus is on the immediacy of the interactional dynamics that emerge in the context of the therapeutic relationship (Allen 2013). This modality of treatment has developed clinical interventions that aim to build or restore the affected peoples' capacity for secure attachments, mentalization, emotion regulation, and impulse control. Specifically, through empathetic mirroring of peoples' neurophysiological, affective, and cognitive states as well as psychological needs, the therapist aims to help them conceptualize the suicidal crisis in terms of a breakdown in their capacity for mentalization (Sharma and Fowler 2018).

Subsequently, suicidal individuals are helped to develop and maintain the functional mechanisms needed to differentiate their own mental experiences from that of others and, thus, become mindful of how the quality of their state of mind influences their behaviors. Therefore, this therapeutic modality aims to provide a safe environment where suicidal individuals can securely identify, explore, and modify their distorted and dysfunctional perceptual lens. This phenomenological exploration and perceptual modification can help them to organize, regulate, process, and

stabilize their mental and interpersonal functioning (Fonagy et al. 2002).

Cognitive and Behavioral Therapy

According to the cognitive-behavioral theory (CBT) of psychopathology, suicide is significantly associated with depressive symptomatology (Routledge 2015). This theoretical model proposes that depressed individuals who also experience a sense of hopelessness about their future are vulnerable to suicide risk. Specifically, suicidal people believe that suicide is the only feasible way out of their unbearable suffering due to their distorted core beliefs that indicate to them that they live in a world in which there is no possible relief for them either now or in the future. Moreover, CBT indicates that these negative core beliefs about the future interact with additional core beliefs about the self and the world (Wenzel and Beck 2008). For instance, a suicidal individual might be thinking that he is a useless and unprotected person who lives in a dangerous world in which he will never find inner peace. That is, the perceptual lens of affected individuals predisposes them to expect more hardship and suffering as they continue to be alive. Consequently, the possibility of immediate escape from their suffering through suicide is perceived to be more desirable than being alive.

CBT is a therapeutic modality that is goal-oriented. It is brief and is methodologically and strategically structured. CBT helps people to understand the functional and disordered associations between their cognitions, emotions, actions, and neurophysiological sensations (Wenzel and Beck 2008). CBT models of suicidality teach the affected people emotion-regulation and problem-solving skills through distraction-related interventions (e.g., mindfulness), thought-suppression interventions, and cognitive-reappraisal interventions. This enables them to cultivate their capacities for distress tolerance and impulse control and then proceed on to work on their suicidogenic core beliefs (Wenzel and Beck 2008).

CBT educates suicidal individuals how to cultivate the capacities needed in order to engage in an operational procedure of cognitive

restructuring through the methodical assessment of the validity and the utility of their dysfunctional cognitive biases. In addition, through a series of behavioral techniques (e.g., behavioral activation, in vivo and in vitro exposure therapy), CBT aims to help suicidal people to change their dysfunctional patterns of behavior with more adaptive ones. A substantial amount of research studies has indicated that CBT is significantly effective in the treatment of the suicidal states of minds as well as in suicide prevention (Bryan and Rudd 2018).

Ideation to Action Theories of Suicide

Fluid Vulnerability Theory

The fluid vulnerability theory (FVT) has been invented and methodologically described in 2006 (Rudd 2006). The FVT provides a theoretical framework that aims to shed light on the underlying processes that contribute to the temporal manifestation of death by suicide risk in the short term as well as in the long term (Rudd 2006). FVT conceptualizes the suicidal risk as an idiosyncratic mixture of acute and baseline factors. Baseline risk factors constitute factors that are generally stable, such as biological predispositions and demographics, which are contributing to the persistence of increased suicide risk in the long run (Bryan and Rudd 2018).

On the contrary, acute risk factors consist of a dynamic interplay between external factors (e.g., environmental stressors), psychological factors (e.g., mental disorders), and operational dynamics that govern the suicidal states of mind. Thus, acute risk factors contribute to the predisposition of suicide risk in the short term (Routledge 2015). According to FVT, the risk for suicide is governed by dynamic features that are fluctuating in reaction to external and internal stimuli. Therefore, the frequency, intensity, and duration of suicidal crises depend on the emergence of an idiosyncratic dimensional mixture of constitutional and psychological vulnerability factors, which is triggered by environmental stressors (e.g., divorce, unemployment) (Rudd 2006).

FVT has incorporated and extended the core theoretical and conceptual principles of CBT regarding the functional formulation of suicidal states of minds as well as attempted and completed deaths by suicide. Precisely, the conceptual framework adopted by Rudd (2006) is termed the suicidal mode. The suicidal mode is an operational construct that integrates functionally and systematically the association between suicidogenic cognitions and dysfunctional emotions, behaviors, and neurophysiological reactions (Bryan and Rudd 2018). More specifically, suicidogenic cognitions represent mental schemas about the self, the world, and the future (e.g., I am defective, the world is a dangerous place, the future is hopeless), conditional beliefs (e.g., if things get terrible and dangerous, I will kill myself), and negative automatic thoughts.

Besides, these suicidogenic cognitions lead to unbearable emotional states (e.g., rage, shame, anhedonia) that are followed by cognitive and behavioral-based dysfunctional strategies (e.g., experiential avoidance, substance abuse, isolation) and neurophysiological states (e.g., vegetative symptoms) (Bryan and Rudd 2018). Furthermore, the underlying functional vulnerabilities that govern the suicidal mode constitute emotion-regulation deficits, perceptual distortions, and cognitive inflexibility that lead to deficient executive and affective functioning. Therefore, clinical interventions should target both of these functional vulnerabilities in order to prevent the transition from suicide ideation to its enactment (Bryan and Rudd 2018).

Additionally, the FVT has presented a series of proposed assumptions that enable the conceptualization of the intensity, frequency, and duration of suicidal crises. In particular, this model proposes that the qualitative nature of a suicidal crisis is time-limited and that the level of distress that could trigger a suicidal crisis differs among people. In addition, following the remission of a suicidal crisis, people are usually returning to their idiosyncratic baseline level of suicide risk (Rudd 2006). This implies that the risk of suicide is also governed by qualitative factors that are resistant to modification over time.

Interpersonal Theory of Death by Suicide

The interpersonal theory of suicide proposes that people are at high risk for suicide when they exhibit an intense urge to kill themselves and they have also cultivated the capacity to act on that self-destructive urge (Joiner and Staff 2015). Therefore, this theory differentiates people who experience suicidal ideation from people that engage in suicide attempts. According to this theoretical model, the driving force of the urge for self-destruction is fueled by two distinct but intertwined intrapersonal constructs, that is, perceived burdensomeness and thwarted belongingness (Joiner and Staff 2015).

Perceived burdensomeness designates the sense of being a burden to other people which is governed by an ego-dystonic (e.g., highly distressing) and distorted sense of being a human parasite. The phenomenology of this experience leads to the formation of a schematic representation that indicates to affected people that the world and its people would be much better if they die and, thus, cease to exist (Joiner and Staff 2015). Thwarted belongingness reflects a sense of intrapersonal isolation and alienation that significantly decreases the sense of orientation, purpose, and meaning in one's life. Moreover, thwarted belongingness implies that the affected individuals feel that they have failed to satisfy their fundamental need for human connectedness, which has life-preservative qualities (Ribeiro et al. 2013).

The simultaneous experience of both perceived burdensomeness and thwarted belongingness has been associated with high-intensity suicidal ideation (Joiner and Staff 2015). Nevertheless, this dynamic is not sufficient enough in order to overcome the primitive instinct of self-preservation and thus enable the transition from suicidal ideation to suicidal action. That is, for a completed suicide to result, the development of the capacity for self-destruction is necessary (Ribeiro et al. 2013).

Humans can develop the capacity for self-destruction, which is governed by high levels of tolerance to physiological pain and significantly low levels of death anxiety. Specifically, suicidal individuals develop the capacity for suicide due to habituation in fear of death, and

psychophysiological pain, and the simultaneous stimulation of opponent operational mechanisms that manifest in reaction to a systematic exposure to fear and pain-inducing stimuli of neurophysiological and psychological nature (Joiner and Staff 2015). For instance, the suicidology literature indicates that repeated exposure to pain through self-injury lowers the inhibitory threshold for suicidal actions at a later time due to habituation to the fear and pain and thus significantly increases the possibility of suicide (Joiner and Staff 2015).

Integrated Motivational-Volitional Model of Suicidal Behavior

The integrated motivational-volitional (IMV) model of suicidal behavior integrates existing data and well-researched operational constructs of different theoretical models of suicidality. IMV provides a conceptualization of the dynamic interaction between distal and proximal vulnerability factors, which contribute to the transition from suicide intention to death by suicide. Precisely, this model consists of three functional phases that conceptualize the multifaceted and dynamic interaction between internal and external vulnerability factors that contribute to the transition from suicidal ideation to suicide attempts and completed suicide (O'Connor et al. 2016).

The pre-motivational phase designates the various vulnerability factors (e.g., mental trauma, divorce, unemployment) that due to their interaction with one another, the biopsychosocial context of suicidality is formed and leads to the transition to the motivational phase in which the phenomenon of suicide intent emerges (O'Connor et al. 2016). For instance, numerous distressing experiences, whether internal or external, can contribute to a sense of defectiveness, failure, and humiliation. When perceptual distortions, and deficient capacities for emotion regulation, problem-solving, and decision-making, mediate such a distressing experience, a sense of entrapment emerges. In the context of further mediators such as the inability for future thinking and a sense of being a burden, disconnected, and alienated from the world and its people, the sense of entrapment intensifies and leads to the perception of suicide

as a feasible solution to ones' suffering (O'Connor et al. 2016).

In the volitional phase, the model conceptualizes the sequential relationship between suicidal intention, suicidal behavior, and death by suicide. Specifically, in this phase, the theoretical model presents cognitive, behavioral, and emotional factors (e.g., impulsivity, rage, capacity for death by suicide) that significantly contribute to the transition from suicide intention to its enactment and, thus, death (O'Connor et al. 2016).

The Three-Step Theory

The three-step theory of suicidality suggests that an overwhelming amount of psychological and/or physiological pain in conjunction with a sense of hopelessness leads to the emergence of suicidal ideation. Furthermore, the intensity of the suicidal ideation significantly intensifies when the phenomenological experience of pain and hopelessness exceeds the affected individuals' connectedness with the living world and its people (Klonsky and May 2015). Specifically, this theory proposes that when people experience high levels of misery, aversion, and pain in their lives, they perceive their engagement with the living world as highly punitive. This leads to the withdrawal of their investment to the living world and its people and, thus, the disengagement with life, which, in turn, leads to further escalation of suicidal ideation (Klonsky and May 2015).

The third step of this model conceptualizes the operational mechanism that enables the transition from suicidal ideation to its enactment and, thus, death. Specifically, this step designates three distinct functional contributory factors that govern the transition from suicide ideation to action. That is, dispositional, acquired, and practical factors contribute to the development of the capacity for suicide, which distinguishes people who exhibit suicidal ideation from people who exhibit suicidal ideation and behavior (Klonsky and May 2015). The dispositional contributors designate genetic factors – for instance, constitutionally low inhibitory threshold, low level of death anxiety, and high pain threshold. The acquired contributors reflect the habituation in death anxiety and psychophysiological pain due to a systematic

exposure to aversive stimuli (e.g., self-injury, victims of chronic abuse). Finally, practical contributors are among others information about, expertness at, and access to lethal means (Klonsky and May 2015).

Evolutionary Perspectives on Death by Suicide

The Altruistic Hypothesis

The kin selection theory proposes that peoples' sequential patterns of behavior have a nepotistic quality. This, in turn, increases the probability that their genetic material would survive through its transmission to the subsequent generations through offspring but also through non-offspring kin (Aubin et al. 2013). The altruistic hypothesis proposes that when the quality of peoples' living existence is perceived (e.g., inaccurately or accurately) to decrease the probability of their kin to pass on their genes, then self-destruction might reflect a sacrifice in the service of a net genetic benefit (Soper 2019).

Moreover, according to De Catanzaro (1984), human beings are most probably to cause their own self-destruction when their reproductive potential is low (e.g., terminal illness, severe psychopathology) and at the same time they perceive that their living existence significantly decreases their inclusive fitness by impeding with their overall genetic kin's reproduction. Therefore, an altruistic death by suicide reduces the reproductive fitness of the victim while increasing the inclusive fitness.

The Bargaining Hypothesis

A substantial amount of research studies related to suicidality has proposed that the manifestation of suicidality reflects costly yearnings for help which could have a functional quality for the people that are enmeshed in conflictual interpersonal dynamics. Specifically, some cases of suicidality might constitute a warning strategy that the affected individuals implement in the context of their interpersonal conflictual bonds (e.g., attachment relations, social group). That is, it might reflect a desperate attempt to communicate to their

significant others or to the members of a social group that they might experience significantly negative consequences if help or change is not offered (Aubin et al. 2013).

Additionally, this warning strategy can function as a genuine (e.g., not manipulative) signal for help, which in turn could motivate caring others to provide appropriate help to the person in need. Precisely according to this hypothesis, people who are exhibiting suicidal behaviors are gambling with their lives. People in need win in a scenario where they survive the suicide attempt and are then beneficially helped, and they lose when they do not survive. This hypothesis finds some support in the widely cited data indicating that most suicide attempts do not have a fatal outcome (Soper 2019).

Pain and Brain Model of Suicide

This model proposes that the phenomenon of suicide among humans might constitute a maladaptive side effect (e.g., negative by-product) of evolved mechanisms whose fitness properties were so powerfully effective that they were worth the cost of suicide. That is pain and cognition (Soper 2019).

Pain is an operational system which aids self-preservation by enabling the human mind and body to immediately and adaptively react to an aversive stimulus. The phenomenological experience of this reaction to aversive stimuli is a strong urge (e.g., affective sensory) to immediately escape from pain and/or experience relief (Soper 2019).

Additionally, psychological pain is intrinsically intertwined with physiological pain motivating humans to react adaptively to threatening stimuli that emerge in the context of their attachment relationships and meaning systems (e.g., cause and effect relationships, internal schematic representations of the word, the self, and others). Psychological pain is widely considered to be as distressful as physiological pain and thus motivates humans to act immediately in order to escape it. That is, aversive stimuli due to their potential damage (e.g., life-threatening, interpersonally threatening) elicit psychological and/or physiological pain that leads to a

psychophysiological disequilibrium (Soper 2019). Consequently, the organism is motivated to immediately find a solution that would lead to the regulation of pain and, thus, to psychophysiological and/or interpersonal homeostasis that significantly increases the probability of survival and reproduction. Thus, the overall adaptive benefit of psychological pain may have been so potent that it outweighs even such a maladaptive by-product as suicide (Soper 2019).

Furthermore, the intellectual mechanisms of the human brain are consensually considered among its most adaptive properties as they have enabled people to create tools, language systems of communication, civilization, and medical and psychological treatments. However, the intellectual capacities of the human brain (e.g., self-consciousness, intentional and logical reasoning, problem-solving) also provide the means to escape pain through self-destruction. For instance, when humans experience intolerable levels of psychophysiological pain triggered by a highly aversive condition (e.g., terminal illness, severe psychopathology) from which escape in the living world is perceived as impossible, they experience a sense of entrapment, defeat, helplessness, and hopelessness. The perception that there is no possible relief from intolerable levels of psychophysiological pain might lead them to use their otherwise adaptive intellectual capacities to escape pain through suicide (Soper 2019).

Conclusion

Death by suicide is a complex, multifaceted, and multifactorial phenomenon, and while it is among the leading causes of mortality globally, it is a preventable cause of death. Nonetheless, due to stigmatization that revolves around suicidality, people in need feel insecure to talk about their experience to their significant others and even seek professional help. That is, usually, suicidal people often suffer in silence, thinking that if they seek professional help, they would be negatively judged and/or considered dangerous. This, in turn, usually triggers feelings of guilt, anxiety, mental

confusion, and, thus, further self-disturbance that increases their risk of death by suicide (Maris 2019). Consequently, there is a need to identify and communicate through every means possible that there are clinical, social, and community interventions that can provide substantial help to the affected people.

Definition

In Christianity, the concept of death is tied to the death of Jesus: Christians typically believe that Jesus sacrificed himself to pay for the sins of mankind and those who believe in him will be forgiven for their sins and gain an eternal life in heaven.

Introduction

A general understanding of Christianity is a prerequisite to exploring the concept of death in this religion. Christianity is considered a monotheistic religion that centers on the life and teachings of Jesus of Nazareth as portrayed in the New Testament, the second major component of the Christian Bible. The Hebrew Bible, called the Old Testament in Christian theology, comprises the first section of the Christian Bible. Although they may differ in the book order, most Christian denominations define the New Testament as 27 books, which include the four gospels, the book of Acts, the 21 epistles, and the book of

Revelation. Christianity is the largest religion practiced in the world. Christian populations make up roughly one third of the world's total population. There are five major branches of Christianity, i.e., Orthodox, Catholic, Protestant, Anglican, and Restorationism. The Roman Catholic Church is the largest church with approximately more than one billion participants. Protestants comprise the second largest group with approximately 500 million adherents. Although the term *Christian* encompasses diverse religious ideas and practices, this entry highlights the shared beliefs regarding crucifixion of Jesus of Nazareth and the role of his death in Christian views.

Most of Christian beliefs are based on the life and death of Jesus. Most Christian groups revere Jesus as the son of God and the incarnation of God. He is the Messiah, or one who is anointed. Followers of Jesus are known as Christians, since they believe that Jesus is the anointed one. According to Christian theology, Jesus died for humanity's sins. His birth, crucifixion, resurrection, and ascension into heaven were required to open the gates of heaven, or salvation, to human beings. Without this sacrifice, people would not be able to join God in eternal life. The traditional Christian understanding of Jesus' birth emphasizes that he was conceived by the Holy Spirit and by Mary of Nazareth, who was a virgin at the time of conception. Beyond his birth, little is known about Jesus' life before he began his public ministry. Jesus started his work as a teacher and healer when he was around 30 years old and spent approximately 3 years doing this work. According to the gospels, he drew large crowds as he traveled and taught in Galilee and Perea. Jesus' final meal with the apostles, the 12 people chosen to spread the word of Jesus' teachings, before his execution is a key event in Christian traditions. During the meal, which is commonly known as the Last Supper or the Lord's Supper, Jesus explained that one of the apostles would betray him. He also shared bread and wine and told his disciples that these were his *body* and *blood*. The gospels of Matthew, Mark, and Luke and the First Epistle to the Corinthians discuss this dimension of the final meal. For example, the Gospel of Matthew (26:26–29) notes:

Now as they were eating, Jesus took bread, and blessed and broke it, and gave it to the disciples and said, 'Take, eat; this is my body.' And he took a cup, and when he had given thanks he gave it to them, saying, 'Drink of it, all of you; for this is my blood of the covenant, which is poured out for many for the forgiveness of sins. I tell you I shall not drink again of this fruit of the vine until that day when I drink it new with you in my Father's kingdom.'

After the final meal, Jesus prayed in the Garden of Gethsemane. Temple guards arrested Jesus, while he was in the garden. Judas Iscariot, one of the apostles, is said to have betrayed Jesus by identifying him to the guards. Jesus was eventually charged with treason and brought before the Roman procurator Pontius Pilate who offered the crowd a choice between Jesus and Barabbas, a political prisoner charged with insurrection. The crowd opted for the freedom of Barabbas and Jesus was sentenced to death. Jesus died in Calvary (also called Golgotha) after being crucified on a wooden cross.

The books in the New Testament explain how Jesus was crucified, died, and buried within a tomb. Three days after his death, Jesus was raised from the dead. The gospels of Matthew, Mark, and Luke all tell of the resurrection of Jesus. Each text, however, emphasizes different points and varies in the details. Christians typically believe that Jesus sacrificed himself to pay for the sins of mankind. Those who believe in Jesus will be forgiven for sins as a result of Jesus' sacrifice and gain an eternal, satisfactory life in heaven. The emphasis of Christianity on heaven (vs. hell) and forgiveness (vs. punishment) may, to some extent, account for lower death anxiety among Christians (also see Krause and Hayward 2014; Lester et al. 2007; Templer 1972).

Although multiple versions of the Ascension exist, accounts emphasize how Jesus bodily ascended into heaven 40 days after resurrection. After ascending to heaven, Jesus sits at the right hand of God, comprising part of the holy Trinity. The Trinity doctrine states there is one God, who is the Father, Son, and Holy Spirit. The bodily ascension of Jesus represents the union of human beings and God and also highlights how Jesus embodies both the divine and the human. The Ascension is discussed at length in Mark 16:19, Luke 24:51, and in the first chapter of the Acts of the Apostles.

Christians remember Jesus' actions at the final meal with disciples in weekly services through the act of Holy Communion, or the Eucharist. The word *Eucharist* can refer to the act itself and/or to the bread and wine used during the act. During Holy Communion, the priest or minister blesses bread and wine (or grape juice) through a series of prayers and actions. After the bread and wine are consecrated, churchgoers leave their seats and go to the front of the church to receive a piece of bread and a sip of wine (or grape juice). This ritual re-creates the moment during the final meal when Jesus gave disciples bread and wine, explaining that these were his body and blood. It reminds Christians of how Jesus "poured out his blood" during crucifixion so that people could be restored to grace.

Evolution of Supernatural Beliefs Regarding Death

Overall, the abovementioned supernatural aspects of death in Christian viewpoint may be explained by evolutionary accounts on supernatural beliefs. The anthropologist Guthrie (1993) observed that humans tend to interpret ambiguous stimuli as having been produced by agents. He further suggests that this perceptual bias is adaptive because it makes humans more wary in their interactions with their environment and consequently reduces the risk of encounters with predators. Guthrie (1993) juxtaposes this finding with the context of a broader theory of religion. Barret (2000) tried to specifically identify the cognitive mechanisms that produce such perceptual biases. Barret coined the term "hypersensitive agency detection device" (HADD) and elaborated: "when HADD perceives an object violating the intuitive assumptions for the movement of ordinary physical objects and the object seems to be moving in a goal-directed manner, HADD detects agency." HADD could contribute to the *formation* of religious concepts (regarding death) by making people identify ambiguous objects as intentional agents (e.g., ghosts or spirits). Additionally, HADD could potentially

reinforce religious concepts regarding death. For example, people who survived a serious illness often reported presence of supernatural entities in their account of what actually happened.

Suicide in Christianity

It is important to present an overall idea of suicide and its ramifications in Christianity. There has been heated debate over the Christian view on suicide (Torgler and Schaltegger 2014). Early Christians believed that committing suicide is sinful and an act of blasphemy. The most notable pro-suicide group was the Donatists, who believed that by killing themselves they could be regarded as martyrs and go directly to Heaven. They were finally declared heretics. Most early theologians of the Catholic Church considered suicide as murder and thus a moral sin in the absence of circumstances that could potentially mitigate the sinfulness of the act. Yet, more recent accounts contend that suicide may not be as wrong as previously regarded. Some Christians posit that one cannot repent of suicide as praying and asking for forgiveness are not possible after death. Higher religiosity in Christian populations may decrease suicidal ideation; however, much of this association may be explained by the social support typically inherent in religious affiliations (e.g., Rasic et al. 2009).

Funerary Rituals

All religions have specific rituals regarding disposing the body of the deceased. Different branches of Christianity (e.g., Protestant vs. Catholic) have different burial rites that may have been evolved in response to different cultural contexts and ecological features. Christians typically believe that Jesus sacrificed himself to pay for the sins of mankind. Those who believe in Jesus will be forgiven for their sins as a result of Jesus' sacrifice and gain an eternal life in heaven. According to these religious teachings, funerary rites should typically

include: (1) an opening statement lead by the priest or minister, (2) prayers and hymns, (3) scripture reading, (4) a remembrance given by a close friend or a family member, and (5) praising Jesus and prayers for the soul of the deceased. Christian burial rituals mainly focus on the deceased entry into Heaven and God's ability to give the grieving strength to cope with their loss. The deceased person is usually placed in the grave on its back. Early Christians adopted the custom of putting the feet toward the east so that at resurrection the reborn can hurry toward sunrise. Wearing black is usually a sign of mourning (see Bedikian 2008). This dress code may be regarded as a social signaling. For example, widows of the deceased are usually, in many cultures, expected to wear black for long periods of time. To remove the black costume early after the death of the deceased husband was considered disrespectful.

Conclusion

In all, Christian beliefs and traditions are diverse and varied. Nevertheless, across denominations Christians share a belief in the importance of Jesus' crucifixion, resurrection, and ascension as the cornerstone of their faith. These phenomena are supernatural beliefs that may be explained using evolutionary psychological theories on supernatural beliefs. For Christians, Jesus' death and resurrection allow the salvation of humanity. Without his death and rebirth, human beings would not be reconciled with God and would be unable to enter heaven or eternal life after death.

Definition

In Islam, death is the transition from life in this world to a truer eternal life in the next world.

Introduction

A nearly universal aspect of human existence addressed by religion is that of death and its meaning. In order to fathom the concept of death

from an Islamic perspective, one should have an understanding of what Islam actually is. There are various definitions and descriptions of Islam. Rather than providing a single definition, one can infer what Islam is, based on what Muslims have made of it in different cultural contexts, social statuses, and historical circumstances. Perhaps, the most robust way to introduce Islam is Quran, the holy book of Islam, which is believed to be a collection of revelations from *Allah* (the Arabic for “God”) as delivered via the angel Gabriel to Muhammad while he was living in western Arabian towns of Mecca and Medina. The Quran consists of 114 chapters and over 6200 verses and describes Islam as: “Upholding equity, Allah, his angels and those with knowledge have witnessed that there is no god but him, the mighty and wise. Indeed, religion in Allah’s eyes is Islam. Those who received the book disagreed among themselves out of jealousy only after knowledge had come to them. Whoever disbelieves in Allah’s sacred verses, (let him know that) God is swift in reckoning” (Quran, 3:18–19).

The Quran emphasizes belief in one just God and posits that disbelief incurs God’s anger. Broadly, the Muslims are those who believe in God’s revelation and submit to God’s will. Much of the contemporary disagreement among Muslims lies under the instances of “God’s will.” By honoring God’s will in this life, Muslims are promised inexhaustible rewards both in this world (*Dunya* in Quranic terms) and the next (*Akhira* in Quranic terms). Many verses of the Quran describe afterlife and death experience. For example, those who fulfill God’s will are expected to directly go to paradise after death. Moreover, a number of verses commend martyrdom and martyrs (*Shahid*), those who die on the path of Islam: “And never think of those who have been killed in the cause of Allah as dead. Rather, they are alive with their Lord, receiving provision” (Quran, 3:169).

Most of the Islamic documents on death and afterlife are based on teachings of the Quran. Death has been mentioned in 36 chapters of the Quran. Despite the diversity of the contexts in which death and afterlife are discussed, the themes of returning to *Allah* and taking full

responsibility for one’s actions are central in these documents. The Quran explicitly contends that one has only one chance, this life (*Dunya*), to prepare for the next life (*Akhira*). Thus, one should do good deeds to be prepared to go to paradise. The dead are believed to be resurrected on Judgment Day for an evaluation of people’s deeds and whether they will go to paradise or hell.

Different interpretations of death in Muslims’ texts have been accumulated throughout the centuries and have produced a complex eschatology that can be divided into the “widely accepted Muslim perspective” and the “Gnostic mystical perspective.” The former view adheres to the teachings of the Quran, guiding believers to stay away from sin. Furthermore, the Quran strongly encourages good deeds (e.g., helping others) and reminds Muslims that each person will be held accountable solely for his or her own acts in this world. The latter view, however, maintains an esoteric conceptualization of death that is direct, experiential, and unmediated. This view is attained by means of mystical practices and through supernatural discoveries.

Notwithstanding the abovementioned complex eschatology and the cited perspectives, there are still enormous variations in Muslim beliefs and practices about death, dying, funerary rituals, burials, and commemorations, some of which derive from differences within the religious tradition, but most of which derive from variations in national, ethnic, tribal, and folk cultures. The diversity of grieving traditions, afterlife beliefs, and burial manners may be explained by the notion that there are no homogenous beliefs in the texts. “Subspecies” of Islam have emerged, possibly because of different selection pressures in different groups that submit to this ideology.

In sum, life and death are interconnected for Muslims and this world is “just the beginning.” Short life of people in this world is a test period in which Muslims are taught to behave correctly, so they are prized with an immortal life of joy and prosperity. Evolutionary psychology has provided insightful findings on religion. The majority of the evolutionary psychologists currently argue that religion originated as a by-product resulting from the interaction of several evolved

psychological mechanisms, and with that initial foundation interacting with cultural evolution, religions are what they are now (Atran 2002). The evolutionary psychological study of death in religious context, specifically Islam, should be pursued using this framework. In what follows, two broad conceptualizations of death in Islam (i.e., widely accepted Muslim perspective and the Gnostic mystical perspective) are shortly discussed from an evolutionary psychological perspective.

First, the *widely accepted Muslim perspective on death* can be explained by its social and individual functions. The thought of being at presence of Allah after death can potentially relieve death anxiety. An enormous amount of social support is also provided for the grieving individuals. This social support is conducive to mental health and facilitates coping with the death of loved ones. In addition, funerary rituals and Islamic rules on body disposal are conducive to disease avoidance and public health. Therefore, Islamic teachings on death, besides being supernatural, provide the society and its individuals with lower death-related anguish, paired with better health in disposing the bodies of the deceased.

Second, *Gnostic mystical perspective on death*, which mostly accentuates supernatural experiential aspect of death, can be partly explained by “hypersensitive agency detection device” (HADD; see Barret 2000) and “minimally counterintuitive” (MCI; see Barret 2004). Barret (2000) has coined the term HADD as “when HADD perceives an object violating the intuitive assumptions for the movement of ordinary physical objects and the object seems to be moving in a goal-directed manner, HADD detects agency.” The by-product account of religious beliefs highlights the importance of the HADD and MCIs (i.e., concepts in which a relatively small number of assumptions are violated, thus grabbing our attention) in religious beliefs regarding death. Specifically, supernatural agents arise as a by-product of HADD and susceptibility to MCIs. Many supernatural, esoteric explanations of death and near-death experience in Islamic texts may be explained by these psychological mechanisms.

Suicide in Islam

It is important to note the Islamic perspective on suicide as well as its psychological analysis. Suicide – the willful taking of one’s own life – is often considered to be morally wrong and an offense against *Allah*. Muslims believe that suicide victims will be punished in the afterlife (Gearing and Lizardi 2009). This is broadly consistent with the finding that suicide attempts are significantly lower among religious individuals (Burshtein et al. 2016). Besides religious teachings on suicide, this topic has become an urgent matter in the past few decades because of the significant increase in the number of incidents in which Muslims have conducted deadly attacks on military and civilian targets that also took the attacker’s life. While religious ideology has been, to some extent, involved in recent suicide attacks, the degree to which it has been a decisive factor is hotly disputed. In fact, some Muslims say that these attackers are not even Muslim and hold unrealistic, brainwashed ideas about the true nature of Islamic teachings. What is almost obvious is that the attackers must think that they are doing God’s work and will be directed to paradise (for an evolutionary account on religiously motivated suicide terrorism, see Liddle et al. 2011).

In Islam, paradise is depicted in several verses, and those who die for a sacred cause (i.e., martyrdom) are welcomed in paradise right after they pass away. For example, paradise is depicted in these verses: “That will neither make the head throb, nor intoxicate. With fruits of their own choice and any flesh of fowl that they desire. And, [for them are] fair women with large, [beautiful] eyes, like hidden pearls, a recompense for all that they did” (Quran, 56: 19–24). It is important to note that religiosity, either Islam or other religions, cannot predict willingness to commit suicide attacks to kill others (e.g., nonbelievers). In fact, Islamic teachings also stress the virtues of humbleness, endurance, gratitude, patience, and obedience to *Allah*. Empirical work also shows a positive correlation between humbleness, honesty, and religiosity in a sample of Muslim individuals (Aghababaei

2012). It is the very subjective understanding of “God’s will” that forms a continuum within Muslims ranging from absolute endurance to suicide attacks.

Funerary Rituals

In Islamic communities, as in Jewish and Christian ones, funerary rituals involve various activities: preparations for death and burial, interment of the body, mourning, and memorial. These rites combine practices prescribed by religious tradition and local cultural customs. Islamic texts have set forth ritual requirements and taboos that Muslims are expected to observe. According to these religious teachings, funerary rites should include: (1) pronouncing the testimony of death, usually in Arabic language (*Shahada* in Arabic), prior to death and turning the dying person’s face toward Mecca; (2) washing and shrouding the corpse in accordance with ritual requirements; (3) performing funeral prayers; (4) conducting the body to the cemetery; (5) burial of the corpse on its right side, with the face turned to Mecca; (6) mourning following religious teachings and local traditions; and (7) visiting the grave. Burial should be performed within 24 h of death. The body is placed in the grave without a coffin and the body is usually wrapped in a piece of white textile. In some cultures, the corpse may be dressed in ordinary but not expensive clothing. It can be clearly seen that culture plays a crucial role in funerary rituals. This also highlights the interaction between the evolution of religious beliefs and cultural evolution. People usually pronounce prayers, while the body is being buried (e.g., “From it [the earth] we created you, then we put you back into it, and from it we will bring you forth again” [Quran, 20:55]). Wearing black, as a sign of mourning, is quite common, but exceptions exist in some areas.

Conclusion

In Islam, death is the transition from this world to the next. In other words, life in this world is a

small but critical part of a larger human existence. The holy book of Islam, the Quran, frequently mentions death, afterlife, and the Day of Judgment. What humans do in this life, the Quran says, will be evaluated and people will be directed either to paradise or to hell. The widely accepted Muslim perspective and the Gnostic mystical perspective on death were discussed. Islamic perspective on suicide and Islamic burial rituals were also shortly described.

Death of Healthy (vs. Sick) Child Followed by More Grief

Bereavement following a child's death

Definition

Parental grief – the suite of emotional and behavioral responses, including deep sorrow, that follows from a child's death.

Introduction

The death of one's children is perhaps one of the most painful experiences humans endure. Although incredibly painful, this experience can still be examined through the lens of evolution. Why did humans evolve to experience such profound distress at the loss of a child? All else equal, would not the parents who recovered seamlessly from their child's death outcompete their suffering counterparts for resources and social partners? Do bereaved parents experience equal levels of grief, or does the intensity of the grief response follow theoretically consistent patterns?

Grief Tracks Inclusive Fitness and Propagation Potential

At first glance, the emotional pain following the death of one's child appears to follow logically from such a substantial loss to inclusive fitness. Children, who share roughly 50% of genes by common descent with their parents, offer a mechanism through which parents can transmit copies of their genetic material to subsequent generations (Hamilton 1964). Indeed, many evolutionary theories of parental attachment are based in the logic that parents invest substantially into caring,

providing for, and protecting offspring precisely because children are vehicles through which parents propagate their genetic material. Parents who lose a child are thus losing an opportunity to transmit their genes. Moreover, parents will not reap subsequent inclusive fitness benefits for any investment (e.g., resources, time) they have already allocated to that offspring.

Given that kin, including offspring, offer mechanisms for individuals to enhance their inclusive fitness, early researchers contended that the human grief response is a natural consequence of these strong attachments (Archer 1999; Parkes 1972). If attachments generally track a social partner's ability to enhance one's inclusive fitness, then grief should be calibrated to the strength of the attachment the bereaved had with the deceased. In the case of a lost child, by this logic, parents should feel immense distress, given that children are one of the primary mechanisms by which parents enhance their inclusive fitness.

However, when allocating investment towards offspring, parents face a series of trade-offs. Because effort, resources, and time are limited, parents who allocate resources to one child are expending effort that might be directed towards other fitness promoting goals, such as investing in the survival of other children or pursuing additional mating opportunities (Trivers 1974). Indeed, parents cannot invest too many of their resources towards one offspring because such ample investment may jeopardize the survival of other offspring or the parent's potential to produce additional offspring in the future. Due to such constraints, parents may calibrate their investment based on offspring's probability of enhancing their inclusive fitness. Offspring who are ill, for example, are less likely to survive and reproduce than offspring who are in better health.

Littlefield and Rushton (1986) contended that the extent of parents' grief following the death of a child should correspond to the probability the child would have reproduced or the child's propagation potential. In a test of this hypothesis, they recruited 263 bereaved parents and demonstrated that grief was more intense following the death of an otherwise healthy child compared to following the death of an ill child. These hypotheses are further supported by pattern of infanticide or the killing of one's young

child. Compared to their healthier counterparts, infants who suffer poor health, exhibit physical deformities, or are born underweight are more likely to be killed by their parents (Ball and Hill 1996). Taken together, these results are consistent with the interpretation that grief intensity is calibrated to the deceased child's propagation potential.

Although the foregone inclusive fitness benefits of losing one's child suggest one explanation for the profound parental grief response, the immense costs of grief still may have severely harmed the fitness of bereaved parents. That is, to explain parental bereavement in terms of lost residual reproductive value commits the sunk cost fallacy because a parent's investments have already been allocated. The time and effort parents already invested in children cannot be compensated by the time, resources, health, and social relationships devoted to grief.

Accounting for the Costs of Grief

The large decrements in grievers' well-being must be offset by other fitness-relevant benefits (Winegard et al. 2014). Otherwise, the protracted and deleterious suite of responses during grief should have been winnowed out by natural selection. All else equal, parents who quickly overcame their child's death would have better competed for resources, status, social partners, and mates than those who allocated greater energy and resources to their sorrow.

Thus, evolutionary-minded researchers have attempted to forward adaptive advantages to exhibiting profound grief at a loved one's death. Archer (1999) argued that the human grief response is a by-product of humans' investment in close relationships. According to his logic, individuals feel distress when separated from loved ones because that distress motivates them to seek out their absent social partners, reunite, and foster their bond through continued investment. In the case of death, however, this distress is in vain. That is, the distress individuals experience during a partner's absence was generally adaptive insofar as it motivated reunion and continued provisioning. In the case of a loved one's death, on the other hand, the individual still experiences this distress response, but the distress is not adaptive.

Archer's (1999) logic assumes that the human cognitive system could not disentangle sources of a loved one's absence. According to the by-product explanation, humans exhibit the same suite of responses (i.e., grief) when a living partner is absent as they do when a partner is dead. However, emotional responses are often quite specific, prompting behaviors that generally would have been advantageous for that particular circumstance (Nesse 1990). Imagine, for example, your child storms out of the house after an intense argument. While they are away, you might feel worried for their safety or upset that they left. Imagine that a day or two later, you learn your child was killed in a car accident the night they left. Your emotional response would likely shift immediately from concern to despair. Or imagine instead you learned your child had left to reside with their friends' parents, with whom you have always felt a sense of rivalry. Your emotional response would quickly shift to relief and perhaps jealousy or moral outrage. These anecdotal examples suggest that emotional responses are quite responsive to cognitive attributions of a loved one's absence.

Indeed, human grave sites extend as far back as 10,000 years ago (Solecki et al. 2004) suggesting human ancestors have long had a cognitive awareness of death. If the human mind is capable of discerning sources of social partners' absences, then this cognitive distinction should have offered a mechanism through which natural selection could weed out the costly misfiring of the separation response. All else equal, individuals who displayed prodigious distress at a living loved one's absence, but not in response to a loved one's death, should have outcompeted those who displayed prodigious distress both when it provided benefits (i.e., in response to mere absence) and when it did not (i.e., in response to death).

More recently, evolutionary-minded researchers have forwarded a novel explanation of the human grief response which posits adaptive advantages to grievers displaying emotional distress and the associated behaviors (e.g., funerary practices) following the death of a loved one. That is, grief serves as a costly, hard-to-fake signal of a person's commitment to the deceased and, thus, the griever's

capacity to form enduring and committed bonds (Winegard et al. 2014). In a sea of potential social partners, humans must decipher which individuals will prove reliable and loyal from those who would abandon the relationship when self-interest favors defection. Because it is very challenging to ascertain individuals' underlying levels of loyalty, human psychology should aim to ascertain predictors of who will likely be a devoted social partner.

Grief may serve as one such cue of these underlying inclinations, precisely because it is so costly. Grievers who are truly distressed forego other fitness-enhancing opportunities (e.g., pursuing resources or mates), thereby honestly signaling their devotion to the deceased individual, who can never repay the devotion. According to the signaling perspective of grief, social partners should perceive individuals who display more intense grief as more trustworthy and prefer them as cooperative allies, compared to those who experience little to no grief at the death of a loved one. Empirical research supports these predictions. Indeed, across a series of experiments, people selected more over less intense grievers as friends and partners for trust games (Reynolds et al. 2015). These findings suggest the human grief response was extended over the course of human evolution because social partners preferred those who exhibited honest displays of their pro-social tendencies through grief.

According to the signaling explanation of grief, bereaved parents may be signaling not only their capacity for loyalty but perhaps also their inclination to be a devoted and nurturing parent. If individuals prefer kindness in both their cooperative alliances, friends, and romantic partners, then the grief response of parents may be treated as diagnostic of such traits. Whether more versus less intense grieving parents are preferentially selected as long-term romantic partners (a context where parenting ability is emphasized) is an open question for future research.

Conclusion

The death of a loved one, including a child, is an incredibly heart-wrenching experience. However, it does not have to be. Although children are one of

the primary mechanisms through which individuals enhance their inclusive fitness, the substantial decrements in fitness due to grief should render intense grief fitness-harming. Thus, evolutionary explanations of the human grief response must account for the immense costs of the suffering to the griever. According to by-product accounts of grief, grief is the misfiring of an attachment response that generally prompted reunion in the case of a loved one's absence. This explanation rests on the assumption that natural selection had no opportunity to winnow out maladaptive separation responses from adaptive ones. However, according to the signaling account of grief, the intensity of grief provides valuable information about the cooperative traits of the griever. That is, parents experience profligate distress following the death of their children because social partners could use these responses to inform their social and romantic choices.

Debating Procreation (With David Benatar)

Anna Wysocki
Oakland University, Rochester, MI, USA

Synonyms

[Antinatalism](#); [Natalism](#); [The Procreation Debate](#)

Definition

Antinatalism is the philosophical position that procreation is unethical. David Benatar and David Wasserman debate this perspective in the book *Debating Procreation*.

Introduction

The permissibility of procreation is a subject that is not often debated, but David Benatar and David Wasserman take on this task in *Debating Procreation* (Benatar and Wasserman 2015). Benatar, an antinatalist, and Wasserman, a natalist, each present arguments supporting their positions and offering critiques to the opposing argument in an effort to answer a philosophical question: Is it wrong to reproduce?

The Procreation Debate

Antinatalism is based on the premise that it should never be permissible to reproduce. However, Benatar distinguishes between the ethics of procreation and the regulation of procreation. He asserts that the moral assertion that one should not procreate cannot be equated to advocating for the removal of the individual's right to

reproduce. Antinatalism is based on the premise that procreation causes harm, and, by not reproducing, harm can be attenuated. Antinatalists argue that being born is always harmful to the individual and others, and that the opposite, not being born, is better. Therefore, Benatar's task is to convince readers of the harmfulness of procreation. In order to do this, he introduces three arguments: (1) the asymmetry argument, (2) the quality of life argument, and (3) the misanthropic argument.

The asymmetry argument contrasts both the harm and the benefit associated with existence and nonexistence. Weights (i.e., positive, negative, or neutral) are assigned to each category, with Benatar contending that being born is always harmful (i.e., that the negatives outweigh the positives). The quality of life argument looks to extend this premise to conclude that all life is harmful enough to equate procreation with unethical behavior. Benatar argues that (1) humans are not good assessors of the quality of their own life because of psychological mechanisms like the optimism bias (i.e., that we are inclined to see positives more than negatives; Andrews and Withey 2012), (2) that there are many small inconveniences in everyday life (e.g., hunger) that are often overlooked, and (3) that there is risk for large-scale harm in every individual's life. He equates the combination of these three factors, particularly combined with the absence of harm that he links to nonexistence, as sufficient evidence that all life is harmful. Finally, the misanthropic argument contends that, not only is procreation harmful to the individual who is being born but also to other humans, other species, and the environment. These three arguments are the foundation of Benatar's premise that procreation is never permissible under any circumstances.

Wasserman begins his natalist argument by critiquing a fundamental assumption used in many antinatalist beliefs; he believes that the overreliance on weighing the avoidance of harm as more compelling than the accrual of benefits weakens the overall antinatalist arguments. Ultimately, he believes that the benefits one can accrue over a lifetime, such as the expected good from the parent-child

relationship, can offset the harm. However, Wasserman stresses that, while he believes there are benefits to procreation, it is never obligatory to procreate nor is it ever harmful to not procreate. Wasserman's pronatalist stance on procreation is more moderate than some other pronatalists and the general public (see Benatar and Wasserman 2015). While he does not believe that procreation is always wrong, he does believe that there are many circumstances where it should not be permissible to procreate.

Conclusion

Without being born, one cannot suffer. Without being born, one cannot experience the joys of life. These are the foundations on which Benatar and Wasserman build their arguments for natalism and antinatalism. While various philosophers have contributed to this discussion, Benatar and Wasserman's *Debating Procreation* provides an excellent overview of the arguments for those new to this philosophical debate.

Deceptive Alarm Calls

Brandon C. Wheeler
School of Anthropology and Conservation,
University of Kent, Canterbury, Kent, UK

Introduction

Although there are potential benefits to be gained through deceptive communication, animal signals overwhelmingly are reliable indicators of some salient property of the signaler or its environment. One reason that honesty tends to prevail is that selective pressures should act on receivers to ignore signals that do not convey reliable

information (Searcy and Nowicki 2005). Thus, in order for there to be an evolutionary advantage for receivers, the benefit of responding to the signal should on average outweigh the cost of ignoring it (Kokko 1997). Because this is *on average*, however, some level of dishonest signaling can be evolutionarily stable in most signaling systems (Johnstone and Grafen 1993). In cases in which the costs of ignoring an honest signal are high relative to the those of responding to a deceptive one, high rates of deceptive signaling can be evolutionarily stable (Searcy and Nowicki 2005). Such a scenario characterizes alarm calling systems: acoustic signals emitted in the presence of a predator alert nondetectors to the predator's presence and allow them to take appropriate action to minimize their risk of a successful predatory attack, while a deceptive caller could elicit the same action in the absence of a predator in order to gain an advantage over receivers in competitive contexts. Because the costs of ignoring alarm signals given in the presence of a predator (potentially death or serious injury) are likely to be much higher on average than those associated with responses to false alarms (energy expenditure plus lost access to a resource), deceptive false alarm calling has the potential to occur at high rates (Wheeler 2009). This provides the rare opportunity for systematic study of both the behavioral ecology of deceptive signaling as well as the proximate mechanisms underlying the behavior.

The Behavioral Ecology of Deceptive Alarm Communication

The use of alarm calls in the absence of predators have been demonstrated in bovids, sciurid rodents, primates, and a number of avian taxa in two main competitive contexts: feeding and mating. In cases in which a food resource goes to the first individual to arrive (scramble competition; Koenig 2002), a false alarm may distract a competitor long enough to give the caller a competitive edge. This has been suggested to be the case in mixed-species flocks of Amazonian birds, wherein sentinel species regularly give alarm

calls that warn of hawk attacks, but also compete with nonsentinel species to be the first to capture flying insects flushed out during foraging; while both species fly toward the prey, the sentinels regularly produce calls that are acoustically similar to those given when hawks are seen, and these typically cause the listener to flee from the non-existent predator and give up the pursuit of the prey (Munn 1986; but see Satischandra et al. 2010). Similarly, fork-tailed drongos (*Dicrurus adsimilis*) in the Kalahari regularly forage in association with other birds and mammals, providing these other species with some antipredator benefits by producing alarm calls when raptors and mammalian carnivores are detected, but also kleptoparasitizing food of the associated species (Ridley et al. 2007). While such kleptoparasitism is sometimes achieved by direct attacks by drongos, false alarms are common in cases in which an attack is a less viable tactic, such as when the target species is relatively large and thus more likely to win a physical contest (Flower and Gribble 2012). Intriguingly, drongos not only deceptively use their own alarm calls to cause other species to abandon their food, but will also mimic the associated species' own alarm calls in the absence of predators to kleptoparasitize their food (Flower 2011).

Deceptive false alarms have also been shown to be an effective foraging tactic for relatively low-ranking individuals competing against dominant conspecifics, who enjoy greater feeding success because they monopolize access to contestable food resources to the exclusion of subordinates (contest competition; Koenig 2002). Among both great tits (*Parus major*) and tufted capuchin monkeys (*Cebus [Sapajus] apella nigrilus*), low-ranking individuals produce deceptive false alarm calls when feeding in association with higher-ranking individuals, causing the dominant to abandon the food patch long enough for the caller to obtain at least some of the contested food (Møller 1988; Wheeler 2009). High-ranking individuals do not need to use deceptive alarms because they can simply displace lower-ranking individuals from the contested food resource (Møller 1988; Di Bitetti and Janson 2001). Likewise, when food is less clumped, lower-ranking

individuals can obtain food by feeding away from dominants; in both tits and capuchins, the use of false alarms decreased when food was less clumped and thus less easily monopolized by dominants.

The use of deceptive alarm calls has also been shown to be a tactic used by males of some species to reduce the chances that females with which they have mated will mate with other males. Male barn swallows (*Hirundo rustica*), for example, are more likely to give false alarms if their mate is absent from the nest during periods of egg-laying, when extra-pair copulations and fertilizations are common, than they are during other periods; they are especially likely to call in this context if another male was recently seen in the vicinity of the nest (Møller 1990). Male Formosan squirrels (*Callosciurus erythraeus*) produce long bouts of false alarms after mating, which cause both the female and neighboring males to freeze, thus increasing the chances of multiple copulations with the female and likely providing an advantage in sperm competition (Tamura 1995). Similarly, male topi antelopes (*Damaliscus lunatus*) produce false alarms when a female attempts to leave his territory after mating (Bro-Jørgensen and Pangle 2010). These deceptive alarms typically cause the female to remain in the calling male's territory and engage in additional copulations with the deceptive caller before finally leaving the territory.

Although these studies show that production of false alarms are often successful in eliciting costly responses in receivers that are to the benefit of the caller, there is also some evidence that receivers may mitigate these costs through counter-deceptive "skepticism" of false alarms. Among tufted capuchins, listeners are less likely to employ antipredator escape reactions to alarm calls given during competitive feeding, when alarms are more likely to be deceptive (Wheeler 2009), than they are in less competitive contexts (Wheeler 2010). The fact that recordings of false alarms played back in noncompetitive contexts elicit antipredator responses at high rates suggests that the decreased response rate may be due to listeners being skeptical of calls given in contexts

in which deception is most likely (Wheeler and Hammerschmidt 2013). Rhesus macaques (*Macaca mulatta*) similarly are more likely to ignore alarm calls from subordinates than from dominants, which the authors suggest may be due to skepticism of callers that are more likely to call deceptively (Gouzoules et al. 1996). Likewise, when drongos repeatedly attempt to deceive individuals of associated species by repetitively mimicking the target species' alarm calls, the targets respond more weakly to successive false alarms (Flower et al. 2014). The drongos, however, are able to take advantage of the fact that the associated species recognize the alarm calls of additional species that the drongos can also mimic; by switching to the alarm call of yet another species, drongos can decrease the targets' skeptical responses to repeated false alarms (ibid.).

Mechanisms of Deceptive Alarm Calling

Due to the potential cognitive implications of deceptive behavior (Byrne and Whiten 1992), the proximate mechanisms underlying deceptive alarm calling have been subject to considerable speculation, but little direct study. In the examples given above, the evidence that false alarms function to deceive listeners is strong, insofar as the calls make listeners behave as if something that is not true is in fact true, which benefits the caller but is costly to the receiver (Searcy and Nowicki 2005). Whether or not callers produce these calls intentionally is less clear. Because intention to manipulate what a receiver believes requires an understanding that other individuals have beliefs at all (second-order intentionality or "Theory of Mind"; Shettleworth 2010), and because of the lack of evidence that these species have such cognitive abilities (Penn and Povinelli 2007), it seems extremely unlikely that the calls are produced with the intention to deceive. However, it is possible that the calls are intentionally produced with the goal of changing receiver behavior, without understanding that the change in behavior is a consequence of the changed mental

state of the target (first-order intentionality; Shettleworth 2010). Evidence for either first- or second-order intentionality would suggest that the calls are not merely functionally deceptive, but in fact are examples of tactical deception (Byrne and Whiten 1992).

While it seems plausible that calls may be produced with first-order intentionality due to relatively simple associative learning (Shettleworth 2010) of the fact that call production is associated with a competitor fleeing or a mate remaining nearby (Wheeler 2009; Flower 2011), in most cases it is difficult to rule out that call production is an unintentional, hardwired response to a given situation. Among the documented cases of deceptive alarm calling, intentional production seems most likely in the case of the false alarms by drongos; the mimicked calls themselves are not innate but develop only with experience (Goodale and Kotagama 2006), and such learned call types are likely under voluntary production (Jürgens 1995). In contrast, in nonvocal learning taxa like nonhuman primates, sciurid rodents, and bovids, vocalizations are species-specific and individuals appear unable to voluntarily choose in which context to produce a given call type because each call type is linked to particular affective states (Jürgens 1995). Thus, the production of false alarms in at least these mammalian species may not be intentional, but an involuntary vocal reaction to the affective state elicited by the competitive context (see Wheeler et al. 2014), which may but need not necessarily be the same state elicited by predators. It is possible, however, that even with this limitation that individuals can voluntarily choose to produce an alarm call when in the appropriate state, although deceptive calling may not be an option for individuals not experiencing such a state.

The only study to date to examine possible mechanisms underlying the production of deceptive false alarms tested whether such calls among tufted capuchins are associated with increases in production of glucocorticoids (“stress hormones”) among subordinates involved in competitive feeding (Wheeler et al. 2014). The study found no support for this hypothesis, although a follow-up

study found that deceptive callers show signs of anxiety in the contexts in which they produce false alarms (Kean et al. [in press](#)). However, because some noncallers similarly show signs of anxiety, it seems unlikely that anxiety simply leads individuals to call involuntarily. It is possible, instead, that certain individuals experiencing anxiety choose to call, perhaps because they have learned that doing so leads to food rewards. Further research is needed, however, on the ontogeny and mechanisms underlying deceptive calling in order to better understand the potential cognitive, emotional, and physiological underpinnings of this behavior. The study systems described above provide an ideal opportunity to study the mechanisms underlying deceptive communication systematically, although it seems likely that there are many cases of deceptive alarm calling that are yet to be documented.

Definition

Declarative knowledge is proposed as the system containing memories of events and factual information.

Introduction

Declarative knowledge is subdivided into semantic and episodic memory that render it as symbolic knowledge system. It affords the individual the capacity to store associations in a single trial and contains knowledge that can be thought and spoken explicitly. Interestingly, declarative knowledge lies outside conscious awareness, until it is retrieved by cues from within the environment. The individual can only become aware of the outcome products of such process since the retrieval process cannot be accessible voluntarily.

Evolution and Declarative Knowledge

Phylogenetically, it can be argued that declarative knowledge appeared later than procedural knowledge. This can be shown by the fact that declarative learning only occurs in higher animals, if not human beings (Ornstein 1991). Ontogenetically, it is demonstrated by the fact that children begin to learn and remember procedures before they do facts (Bloom and Lazerson 1988). Also, natural selection has shown that procedural skills are more important for survival than declarative facts (Dudai 1989). Hence, it is not reasonable to assume that knowledge of facts evolved before the knowledge of skills. It is not clear how evolution of brains and brain modules proceeds. However, it cannot be assumed that the evolution of memory and of the visual system has the same background, for these faculties are concerned with quite different tasks (Gibson 1979). Taken together, the present theory states that in both vision and memory, a declarative subfaculty is part of the outcome, and that both systems are far more procedural in nature than it has been assumed so far. A tentative conclusion that can be made considering all this is that the procedural/declarative distribution is a feature of certain brain modules that exist independently of the content of those very brain modules. The distribution is a principle that supposes an organization of a certain kind in certain brain modules. If this hypothesis is valid, then an imbalance in the attention of cognitive

psychologists and neuroscientists given to the procedural subsystem and the declarative subsystem can be found in the visual system as well as in the memory system (Goodale 1992).

Brain-Damaged Patients

Declarative memory stems from the phenomenon of category-specific impairments in semantic memory. A double dissociation has been found in brain-damaged patients between their knowledge of respectively living, for instance animals and fruits, and nonliving, such as tools and clothes. Saffran and Schwartz (1994) argue that this deficit actually reflects not a distinction between living and nonliving things but a distinction between perceptual and functional characteristics of members of the impaired categories. The ground for distinguishing between two animals as similar as a leopard and a panther is the difference in visual characteristics, while the ground for distinguishing between two tools is their different functions. Once more, a difference between action and perception is found in a presumably single system. Category-specific impairment for functional attributes of objects is not a deficit of procedural memory since tool use is intact. In terms of the present theory, this could imply that even within semantic memory of declarative system, procedural aspects are a fundamental part of the system (Bechtel and Abrahamsen 1991). However, to draw any conclusions from this speculation would be premature until it becomes clearer what memory system exactly is damaged in these cases and how it connects with other systems.

One-Trial Learning

In the context of human declarative memory, one-trial learning implies that a fact is comprehended after one presentation (Johansson 1973). But it is also possible to know how to do something after one presentation (Baddeley 1990). For instance, patients who suffer from Korsakoff's syndrome, a form of amnesia typically associated with alcoholism, when they experience a physical painful event, their brain tends to store the unpleasant

outcome in declarative memory. In future situations of the same nature of events, the patient will avoid the event, but they will not be able to justify why, as they will not be able to remember the background information which have caused their outcome behavior.

Conclusion

It has been argued that declarative memory evolved from procedural memory and it constitutes a part of it. Some of its aspects might be reduced to procedural memory. It is both phylogenetically and ontogenetically younger than procedural memory; it is shown to be possible to model declarative knowledge in procedural systems and neural networks, and in some cases one-trial. Learning can function within the procedural system. This notion suggests that declarative knowledge is made possible by procedural knowledge; interpretively, declarative knowledge could be considered a special case of procedural knowledge.

Definition

A great deal of evidence indicates that human society has experienced a slow and steady decline in both interpersonal and intergroup violence as cooperation, empathy, and peaceful resolution of conflict have become more dominant.

Introduction

The emergence of *Homo sapiens sapiens* was a watershed moment in the natural history of the planet. Highly mobile populations of modern

humans quickly replaced all of the other contemporary hominins they encountered, probably through a combination of violent and nonviolent means, and dramatically reshaped every environment they entered. However, human social groups are marked by extensive intraspecific cooperation, empathy, and nonviolent resolution of conflict, at least compared to our closest relatives, the other extant apes. There are several theories that have been developed to explain the decline of violence in the human species that are not mutually exclusive; in fact, synergy among them is likely.

Intelligence, Communication, and Language

Intelligence and sophisticated communication are necessary preconditions for prosocial cooperation. While true referential communication – nouns and adjectives – has been observed in several nonprimate mammal species (and may also exist in birds), complex social communication is a hallmark of primates (Slobodchikoff 2012). The apes have taken this further to include body language and gestural communication that exhibits personal variation and regional dialects (Byrne et al. 2017). A phylogenetic analysis has revealed that, in primates, the size of the vocal repertoire is closely associated with both group size and time spent in close social contact (McComb and Semple 2005). The evolution of intricate sociality and sophisticated communication seems to be linked, perhaps inextricably.

Esther Herrmann and colleagues take this idea further and propose the *cultural intelligence hypothesis*, which holds that the key difference in intellectual capacities between humans and other animals is not in general intelligence, but in specific cognitive abilities related to our sociality (Herrmann et al. 2007). This includes our social intelligence, the ways in which we communicate, understand, and interact with our fellow humans, but also our *meta-social* intelligence, that is, the ways in which we form hierarchical subgroups, communities within communities. The activation and ecological shaping of innate

abilities is of key concern to this question because primate behavior is not strictly programmed, but rather extensively learned, and socially so.

In 1993, Frans de Waal and Denise Johanowicz performed a pioneering cross-fostering experiment that demonstrated the connection between prosociality and learning. They took juvenile rhesus macaques, which are fairly aggressive and not prone to displays of apparent social reconciliation, and allowed them to be raised with stump-tail macaques for 5 months, a species known for peaceful conflict resolution. The results were dramatic. In addition to acquiring various food preferences and strategies, etc., the cross-fostered rhesus macaques also picked up the behaviors described as “peaceful reconciliation.” These habits persisted long after they were returned to their original troop of conspecifics. This study demonstrates that primate behaviors are not purely genetically encoded but take shape through learning within a social milieu. That the reduced aggressiveness persisted even after they lost other learned habits hints that sociality may involve non-genetic (e.g., hormonal) mechanisms of self-reinforcement. In sum, elaborate communication and social collaboration is a driving force of intelligence across diverse clades of birds and mammals and culminated in apes and hominins.

Competition Drives Cooperation

It has been known for some time that, among primates and possibly other mammals, there is a rough correlation between group size and brain volume and this has led to the “social intelligence” theory of primate intelligence (Reader and Laland 2002). However, Byrne and Whiten (1988) emphasize that social intelligence is not always prosocial and may just as frequently be “Machiavellian” in nature. Importantly, these two notions are not necessarily in tension (Stewart et al. 2016). In fact, prosocial behaviors and manipulative behaviors involve many of the same cognitive abilities related to the interpretation of behaviors and mental states, understanding the past in order to predict the future, etc. Whether we strive to successfully work *with* or *against* someone, the necessary interpersonal skills overlap considerably.

Gavrilets (2015) has modeled the role of collaborative and competitive skills in the evolution of the human brain and found that the two are not just overlapping, but reinforcing. Conflict *between* groups sets up strong selective pressure for the emergence of within-group cooperation leading to an evolutionary arms race of “cooperative competition.” Groups of hominins competing against one another led to groups of humans cooperating with one another.

Cultural Group Selection

Although cooperation is a successful strategy for survival, flourishing, and biological fitness, it can nevertheless be purely self-directed in nature. Human cooperation goes beyond this into true prosociality in which individuals act for the benefit of others without regard for the immediate benefit to oneself. The extensive prosociality of humans, not to mention human altruism, has been a conundrum for evolutionary science since Darwin first proposed natural selection as the primary mechanism of adaptation. The problem of deception, cheating, and free-loading often overtakes cooperation in attempts to model the evolution of cooperation in animal species. Leticia Avilés (2002) has proposed that freeloaders can theoretically be kept rare by frequency-dependent group-level selection. This selection process may similarly function to restrain the proliferation narcissistic sociopaths (Lents and Trivers 2018). Christopher Boehm (2009) and others have argued that collective action to enforce rules and punish cheaters has resulted in the evolution of an egalitarian social structure among human societies dating back to at least the Paleolithic.

Nevertheless, however much between-group competition drives within-group cooperation, the emergence of collaboration, collective action, and altruism is difficult to model without the invocation of group-level selective forces. Although first fully articulated by the political and economic theorist Friedrich Hayek (Henrich 2004), a phenomenon called Cultural Group Selection (CGS) has its root in *The Descent of Man* (Darwin 1871). Darwin noted that the biological differences

between groups of humans are negligible compared to the differences in cultural practices and therefore latter are far more determinant of success when the groups clash. Because this phenomenon does not appear true in other species, human may have evolved in a unique selection environment, rendering obsolete selection models based on data from other animals. Not surprisingly, CGS has met with strong criticism (West et al. 2011).

Recently, Richerson et al. (2016) have mounted a vigorous defense of CGS as a key selective force in the emergence of human cooperation. This defense is predicated on the assertion that cultural traits, i.e., memes, can evolve in a Darwinian fashion (Dawkins 1976). To function in this way, CGS requires that a species meet the following criteria: (1) possesses high capacity for social learning, (2) exhibits conformist behavioral tendencies, (3) gains strong selective advantage from cooperation, (4) engages effective punishment of social deviants, (5) reputation (prestige) leads to reproductive success, (6) groups marked by symbolic, non-biologic differences, and (7) has established “institutions” through which collective action can bring group benefits. Interestingly, CGS relies on the actions of gene-level elements to facilitate group-level selection, a point underscored by Richard Dawkins’ coinage of the term *cultural meme* within a larger defense of the gene-centric view of natural selection (Dawkins 1976). It is worth noting that most scholars of human cooperation agree with many of the individual tenants of CGS, if not the entirety of the theory (Singh et al. 2016; and for a comprehensive discussion of some the counter-arguments to CGS, see West et al. 2011).

Self-Domestication: Survival of the Friendliest

An even more specific theoretical framework for the emergence of highly cooperative and nonviolent social structures in humans is the notion of self-domestication. This theory holds that the behavioral changes that occurred in animals as they were domesticated, such as increased docility, are similar to the “civilization” of human beings over the last 200–500 ka. Although this possibility was obliquely mentioned by Darwin (1871), it was first fully articulated by Franz Boas (1901). In the time since then, the possibility has

been raised that animal domestication may have been less something that humans intentionally did to other species, and more something that those animals did to themselves by pursuing the unique ecological niche of mutualistic cohabitation with humans. The very specific selective pressure of that niche resulted in what could fairly be called self-domestication (Zeder 2006, 2012).

Some of the features of domestication that cut across many species are reduced external ears, snouts, teeth, and brain size; curly tails, floppy ears, and skin depigmentation; as well as the all-important behavioral changes of increased docility, feminization, and neotany. That such specific features appeared in such divergently domesticated species argues for a common mechanism and has been called *domestication syndrome* (Wilkins et al. 2014). The search for this common cause has implicated deficits in neural crest cells during embryonic development and a host of candidate genes (Sánchez-Villagra et al. 2016).

The notion that modern humans are the result of self-domestication syndrome is rapidly gaining support. The anatomical evidence alone is striking: modern humans have a reduced jaw, brow, nasal projection, teeth, and cranial capacities, compared to our archaic forebears (see Fig. 1). In addition, Theofanopoulou et al. (2017) have identified a suite of candidate genetic changes for domesticated species, including humans, that may have mediated this transition.

Central to the theory of self-domestication is the notion that reduced aggression brought gains in biological fitness. Despite the nuance brought by the theory of cultural group selection, fitness, inclusive or otherwise, must be the output for adaptive natural selection. Whether mammals cuddling for warmth or hominins working together to hunt megafauna, personal benefit is key to the decline of aggression. Inspired by the theory of endosymbiosis that made her famous, Lynn Margulis remarked that “Life did not take over the globe by combat, but by networking” (Margulis and Sagan 2000). When applied to the emergence of modern human behavior, this idea is frequently expressed as “survival of the friendliest,” a term that, tellingly, grew out of research into intergroup contact theory (Pettigrew 1998).

In the past 10 years, substantial progress has been made in fields as diverse as developmental biology, comparative behavior, neuroscience, paleoanthropology, cognitive psychology, and of course evolutionary psychology, toward supporting the notion that reduced aggression, enhanced cooperation, and in-group prosocial behaviors were *naturally selected features* in the emergence of behavioral modernity (Hare 2017).

Aggression and Testosterone

The elephant in the room with the survival of the friendliest paradigm is the reality that human aggression and violence almost always aligns well with adaptive benefits (Buss and Shackelford 1997; Shackelford and Weekes-Shackelford 2012). However, the realization that aggression is actually comprised of two very different behavioral modes, proactive aggression and reactive aggression (Poulin and Boivin 2000), may allow a breakthrough of this apparent paradox. Wrangham (2018) has recently argued that these two modes of aggression may have been differentially shaped by natural selection over the last 200–500 ka. While proactive aggression (sometimes called predatory attack) refers to the willful, planned attack focused on obtaining or achieving a goal with clear survival benefits, reactive aggression (sometimes called affective violence) is a response to an immediately threatening stimulus and is directed only at escaping or neutralizing the threat. Under this model, the recent natural history of our species has seen a decline of reactive aggression, not proactive aggression. This can be expressed as gains in self-control, peaceful conflict resolution, etc. Intriguingly, calculated proactive aggression may have even contributed to the decline of reactive aggression through capital punishment. As Boehm (2000) has argued, the majority of the victims of capital punishment in traditional societies are those who fail to control their reactive aggression.

At the same time, there may also have been a turn away from direct physical violence toward subtler forms of social manipulation collectively referred to as *indirect aggression* (Ingram 2014). While it remains to be examined if the switch to indirect forms of aggression is more of a cause or

Decline of Violence,

Fig. 1 Salient craniofacial differences between modern humans and Neanderthals (top) and between dogs and wolves (bottom). Figure taken from Theofanopoulou et al. 2017

an effect of the decline of violence, the phenomena of reputation, status, gossip, and coercion enact some of the same social functions in humans as aggression does in other species. In summary, it seems plausible, then, that a combination of domestication syndrome and cultural group selection acted to reduce reactive aggression and promote self-control in humans, while cognitive advances allowed more sophisticated forms of proactive aggression, which can either promote or restrain violence, depending on context.

While a great deal of solid theoretical work has been done on the decline of violence, most is focused on the ultimate adaptive gains, with

comparatively little progress on the proximate mechanisms (the exception being recent work on the genetics of domestication syndrome in humans, see Theofanopoulou 2017 and references therein). However, new insight into the mechanism of cooperative prosociality has emerged from the study of behavioral endocrinology. Specifically, average levels of circulating testosterone have been linked to aggression in several mammal species including the African apes (Book et al. 2001). There is evidence that circulating testosterone has steadily decreased in modern humans over the last 100 ka, and possibly extending back 1–2 Ma (Cieri et al. 2014). This evidence comes

from the study of emerging skull features that have been linked to lower testosterone including the reduced prominence of the brow and jaw, smaller teeth and eye sockets, and rounding of the face. While it is not currently possible to measure testosterone in fossilized remains, the evidence for “craniofacial feminization” in our recent ancestry is compelling.

The careful analysis of Wardecker and colleagues (2015) adds important nuance to the role of testosterone and estrogens. For example, “in species where social dominance is integral to mating success, testosterone is very tightly linked to mating effort; in species where social cooperation is essential for mating success, testosterone is more loosely linked to mating effort.” (Wardecker et al. 2015). In addition, while testosterone is linked to dominance toward sexual rivals in human males, it is also associated with affiliation and cooperation with males that are *not* sexual rivals. Testosterone also seems to play a different role in short- versus long-term mating, although, as noted by Wardecker et al., the causal arrow could also point the other direction. Hormones don’t just influence social behaviors, they are influenced by social behavior.

While a great deal of work remains to parse out the role of the respective ultimate and proximate causal mechanisms, the social and cultural milieu of the last 200 ka of human history has been marked by increasing empathy, prosociality, altruism, and in-group cooperation. While violence has always been a part of our culture, it has been in steady decline as our species transitioned to so-called behavioral modernity, a transition that continues to the present (Pinker 2011). Understanding the social, cultural, genetic, and hormonal roots of this decline offers great promise for continued progress on the pacification and long-term success of our species.

Definition

Estimates of offspring number of homosexual individuals.

Introduction

Nearly all literature on the evolution of human homosexuality refers to the lowered reproductive success of homosexual individuals. According to Potts and Short (1999, p. 74) “homosexual behavior is the antithesis of reproductive success.” Such emphasis is understandable, given the crucial importance of decreased reproductive success for what is often dubbed “the evolutionary paradox” or “the evolutionary puzzle” of homosexuality. Yet, it is striking how little research has been done to determine the actual reproductive fitness of homosexual men and women. For that reason, Ehrlich (2000) speaks of the “putative direct negative effect on fitness.” Others have also called the empirical evidence for the relative fitness relation between homosexual and heterosexual individuals weak. Moreover, the estimates in the existing studies do diverge.

Empirical Evidence on Offspring Number

Before discussing the main findings on offspring number of homosexual individuals, it is useful to outline why the topic has not been researched more thoroughly. First, many researchers seem to think there is no need to study extensively that what is obvious to any thinking person, namely that the reproductive success of homosexual individuals is lower than that of heterosexual individuals. Hence, it is assumed rather than shown that homosexual individuals have a reduced reproductive success. Often, scholars write that homosexual men have fewer children than heterosexual men, but without referencing this claim. Usually, it is acknowledged that some homosexual people have biological children, but it is also argued that this does not do away with the fact that their reproductive success is on average lower than that of heterosexual people.

Second, it is also assumed that the need for an evolutionary explanation for homosexuality does depend on the decreased reproductive success of homosexual people, but that it does not depend on how much lower this reproductive success is, at least as long as it is substantially lower, which it is usually assumed to be. So the evolutionary study

of human homosexuality does not directly motivate the search for precise estimates of the reproductive success of the homosexual population. Of course, this can change in the not too distant future, but until now, no evolutionary theory needs to establish how strong the selection pressure is; they only need to know that the selection pressure is strong.

Third, changes in reproductive behavior in the West since the early nineteenth century make it difficult to use Western samples for determining the historical fitness effects of human traits and behaviors. For instance, socioeconomic status in the West negatively correlates with reproductive success (Skirbekk 2008), whereas it is supposed to have a positive effect on reproductive fitness in other parts of the world. Likewise, quite a few researchers think that the reproductive success of homosexual individuals differs across time and cultures (Vander Laan et al. 2012), in large part because Western cultures may be outliers with regard to social norms about reproduction, and how these norms impact on the reproductive behavior and choices of homosexual individuals. If they are right, this is a good reason to be cautious about the generalizability of the data gathered in Western cultures. At the same time, it can also deter from doing research on the reproductive success of Western homosexuals (the most accessible population for most researchers), since the findings of these studies may not be very relevant for evolutionary hypotheses (Vander Laan et al. 2012).

Still, some research has been done. Many evolutionary hypotheses on human homosexuality invoke kin selection and inclusive fitness and hence they rely on the reproductive success of the relatives of homosexual individuals. This entry will not deal with data on indirect reproductive success, but focus solely on the direct reproductive success of homosexual individuals.

An Australian study from the early 1970s found that 95 homosexual men above 40 had 37 children in total, which is significantly lower than the number of children one can expect for a group of heterosexual men of the same age (the fertility rate in Australia was in 1972 around replacement level). Twenty-five years later, Van de Ven et al. (1997) reported similar numbers in

Australia, at least for older homosexual men (defined here as men above 49). A little more than 50 % of these older homosexual men had children. However, younger homosexual men were much less likely to have children. This may be evidence of a change in reproductive success among gay men in the West at the end of the twentieth century, something that others had already hinted at. The hypothesis that such a change occurred was corroborated by studies in the USA. In 1978, researchers estimated that the reproductive success of homosexual men was one fifth of that of heterosexual men (Bell and Weinberg 1978). Less than twenty years later, a new study found that the reproductive success of homosexual men was even lower: only 10 % of that of heterosexual men (Hamer and Copeland 1994). In 2005, the participants of an English study reported direct reproductive success that was only 1 % of the reproductive success of heterosexuals (King et al. 2005). The very few studies done in other cultures also show lower reproductive success for those men who are primarily attracted to men. According to Vander Laan et al. (2012), the reproductive success of the Samoan fa'afafine (men primarily or exclusively sexually attracted to men) is very low. However, it is important to note that on Samoa most men who identify as gynophilic do have sex with the fa'afafine. The homosexual behavior of these "heterosexual" men does not seem to affect their reproductive success (Vander Laan et al. 2012).

So, all available studies consistently show that homosexual men have fewer children than heterosexual men, although there are not many studies and nearly all studies have been done in Western societies. Still, reproductive success among homosexual men seems to vary considerably. Some of this variation is geographical, other variation is historical. Compared to older studies, recent studies indicate lower numbers of biological offspring in homosexual men, which may be caused by greater tolerance toward homosexuality in Western cultures and a general decline of the fertility rate in the West.

There is a huge literature on the evolution of *male* homosexuality. Human *female* homosexuality is less theorized about. The very few studies

that do address that issue again tend to assume that the reproductive success of homosexual women is lower than that of heterosexual women, although theoretical arguments are advanced for why the reproductive success of homosexual women will probably be higher than that of homosexual men (more fluidity, less freedom of choice, possibility of sexual intercourse without sexual attraction) (Apostolou 2010). While the data on reproductive success of homosexual men are already scarce, the data on homosexual women's reproductive success are even scarcer. A recent report from the Williams Institute (Gates 2013) shows that homosexual women are more than four times more likely to have biological offspring than homosexual men, even though their reproductive success is still considerably lower than that of heterosexual women. Still, the evolutionary relevance of these numbers is not clear, given the obvious involvement of new reproductive techniques (IVF and other forms of donor insemination).

Conclusion

It is widely assumed that homosexuality leads to decreased reproductive fitness. The empirical evidence for this assumption is weak regarding the reproductive fitness of homosexual men and very weak for the reproductive fitness of homosexual women. Still, it seems that the few studies that looked into the offspring size of homosexual people do point in the direction of a decreased reproductive success.

Defection

Simon T. Powers
Edinburgh Napier University, Edinburgh, UK

Synonyms

Cheating; Exploitative; Free riding; Noncooperative; Selfish

Definition

An action that can increase an individual's payoff but that results in a socially inefficient outcome.

Introduction

In social interactions, there is often a conflict between what is immediately good for the individual as opposed to what is good for the group of interacting individuals as a whole. Such situations are known as social dilemmas (Dawes 1980) and arise because actions that immediately benefit one individual may nevertheless lead to inefficient outcomes. Consider trade or exchange, for example. Cooperation would involve fairly representing the goods being offered and honoring the terms of the exchange by, for example, not simply taking the goods of the other party by force and giving nothing in return. Defection, on the other hand, would involve misrepresenting the goods being offered or taking the goods of the other party by force. Although the total payoff to the pair of traders is maximized by cooperating, either individual can immediately gain by defecting. This occurs even though defection leads to an inefficient outcome in which each individual is worse off than if they had cooperated.

But yet no society would function if individuals always defected and did not cooperate. This problem occurs across biological taxa, from microorganisms through to social insects and humans. A vast body of research in anthropology, computer science, economics, evolutionary biology, and sociology, as well as evolutionary and social psychology, is concerned with finding conditions that take away the benefits of defection and promote cooperation.

Formalizing Defection Using Game Theory

The outcomes of defection for the actor and for the group are commonly formalized using game theory, which uses mathematical models to analyze the outcomes of strategic interactions between individuals. Table 1 shows the payoff matrix for a single-shot two-player interaction, in which each individual may either cooperate or defect. The game is symmetric, meaning that the identity of the players can be swapped without affecting the outcome.

Defection, Table 1 The payoff matrix for two-player symmetric games. Payoffs shown are for Player 1

	Player 2 chooses cooperate	Player 2 chooses defect
Player 1 chooses cooperate	R	S
Player 1 chooses defect	T	P

The payoff that a player receives is a measure of reward. This reward could correspond to a psychological reward or the economic concept of utility, or to biological or cultural fitness. Individuals are therefore assumed to try to choose actions that maximize their own payoff, whether this is through learning the consequences of actions, or through genetic or cultural evolution.

In this payoff, matrix R represents the reward for mutual cooperation; S represents the sucker’s payoff that the actor receives when it cooperates but its partner defects; T represents the temptation to defect – the payoff the actor receives when its partner cooperates but it defects on that cooperation; and P represents the punishment payoff for mutual defection. When $R > P$, mutual cooperation leads to a higher payoff for each player than mutual defection. If $2R > S + T$ and $R > S$, then mutual cooperation yields the highest total payoff for the pair and is hence the most efficient outcome. Given that these inequalities hold, social dilemmas occur when (1) unilateral defection gives a higher payoff to the defector than mutual cooperation ($T > R$) and/or (2) mutual defection gives a higher payoff than unilateral cooperation ($P > S$). Where only condition 1 holds, this is known as a snowdrift or chicken game. Where only condition 2 holds, this is known as a stag hunt game. Where both conditions 1 and 2 hold, the situation is a prisoner’s dilemma. In all of these games, there is a tension between defection, which can give a higher payoff to the individual, and cooperation, which gives a socially efficient state. This leads to the question of why individuals would not defect.

Theories for Why Individuals Would Not Defect: Kinship and Reciprocity

Much of evolutionary psychology is concerned with the evolved psychology of human hunter-gatherers. The hunter-gatherer social environment of living in small, mobile foraging groups (Boehm 1999) corresponds to the Environment of Evolutionary Adaptedness in which our species has spent most of its evolutionary time. In this environment, individuals relied heavily on cooperation with their group mates in order to obtain food for themselves and their families. This would have resulted in a value of R in Table 1 much greater than P . Evolutionary psychology then draws upon two classes of theory for why defection would not be favored.

The first is kinship. Individuals would often interact with their extended families. In such cases, the theory of kin selection from evolutionary biology (Hamilton 1964) tells us that a genetic predisposition to cooperate rather than defect can be favored due to the fact that relatives share genes. This means that when interactions are between relatives, a gene to cooperate helps copies of itself in other individuals and so spreads in the population. In other words, when interactions are between genetic relatives, then individuals in cooperative families will enjoy the payoff R , whereas individuals in families that defect will receive the smaller payoff P . The same argument can also apply when the tendency to cooperate or defect is transmitted culturally through social learning, rather than genetically. In that case, we can speak of the cultural relatedness between interacting individuals (Boyd et al. 2011).

The second, and complementary, theory is reciprocity. This theory originates from classical game theory in economics. It arises from the observation that social interactions are typically not one time only, single shot. Rather, most interactions are in fact repeated. Formally, the game in Table 1 then represents a stage game that is repeated for a number of rounds.

Repeated games allow for conditional strategies in which individuals condition their own actions on the past actions of their partner. A

strategy specifies the action that an individual will take for a given history of its partner's actions. The folk theorem of game theory (see, e.g., Binmore 2005) tells us that if the interaction is repeated for an indefinite length of time, and if individuals have sufficient knowledge of the past actions of their partners, then any strategy which gives more than the minimax payoff can be an equilibrium. The minimax payoff is the payoff that a player receives when its partner tries to minimize that payoff. In Table 1, the minimax payoff would be the payoff that an individual receives if its partner always defects. Consequently, any strategy in which individuals do not always defect results in a higher payoff to each individual. Such a strategy can therefore be an equilibrium even when individuals are concerned with only maximizing their own payoffs. The reason is that any individual who deviates from the strategy can be punished by having its payoff reduced to the minimax payoff through defection by its partners. If an individual defected, then it would subsequently always receive defection from other individuals, limiting its future payoffs to P or S , which are both smaller than the payoff R from mutual cooperation. The threat of being defected against can therefore stabilize cooperation when interactions are repeated.

This theory of cooperation under repeated interactions was later popularized in evolutionary biology by Trivers (1971). The tit-for-tat strategy advocated by Axelrod (1984) is one example of a conditional strategy. However, in general there will be a very large number of other strategies that give more than the minimax payoff and so which can also be equilibria.

What is needed for this result to apply in a real-world scenario is that the game is indefinitely repeated and that individuals have sufficient information about the past actions of their partners. In hunter-gatherers, interactions were effectively repeated for an indefinite number of times. This is because individuals relied on interactions with their group mates to survive, and no individual could predict the time of its death. Individuals also lived in close-knit communities where they repeatedly

interacted with the same individuals. This made it easy for them to obtain information about the past actions of other group members.

The Effect of Defection on the Evolved Psychology of Humans

The social environment of hunter-gatherers would have selected for psychological traits to detect defectors. Individuals would be selected to have a propensity to obtain and spread information about the actions of other group members, for example, through gossip. The spread of information would be facilitated by certain institutional rules that groups developed (North 1990). An example of this is the institutional rule of the whole group discussing around a campfire each evening. Individuals would also become sensitive to what other individuals thought about themselves, i.e., their reputation.

Because the folk theorem demonstrates that there will be a large number of possible equilibria, individuals would also be selected to coordinate their actions to ensure that they reached an equilibrium that yielded a high payoff to them. In other words, each individual would benefit from its group coordinating on an equilibrium in which cooperation was frequent and defection rare. This would select for individuals to create institutional rules and norms that coordinated actions onto a high payoff equilibrium. For example, by using low-cost coordinated punishment against acts of defection, such as ridicule and ostracism (Boehm 1999).

Defection in Large-Scale Societies

The origin of agriculture led to individuals living in much larger social groups. This meant that there was a lower genetic relatedness between interacting individuals. It also meant that it became harder for individuals to obtain information about the past actions of group members. Why, then, is defection not more frequent in large-scale societies? Some scholars argue that defection would actually be individually advantageous but that

individuals do not defect because they still carry the evolved psychological traits from our past hunter-gatherer environment. Under this account, our evolved psychology is “misfiring” in the new environment of large-scale societies. This “misfire” argument was popularized by Dawkins (1976). Other scholars contend that defection is not advantageous even in large-scale societies, because groups have created institutions that still allow the conditions for cooperation under the folk theorem to be satisfied (e.g., Greif 2006).

Conclusion

The possibility of defection threatens the potential gains from cooperation. The ecological and social environment of hunter-gatherers would have selected for traits that supported cooperation through kinship and reciprocity. This would include equipping individuals with a psychology that made them sensitive to their own reputation and the reputation of others. It would also have favored traits that facilitate the spread of information about the past actions of group members, such as gossip. To what extent these traits continue to be adaptive in the new environment of large-scale societies is a current research question.

Definition

Biomechanical and psycho-physiological defensive response by the human body to a close quarters physical attack.

Introduction

All attacks and assaults on human beings are dangerous; however, the most dangerous attack is one a person doesn't see coming. Because predators stalk their prey, they often decide where, how, and when they will engage their target (Meadows 2007). This creates a dynamic where a victim is surprised by sudden violence given a lack of awareness of the attack and the subsequent and overwhelming psychological, emotional, and physical trauma during the critical incident. A blitz-style or ambush-style attack is one without a person's consent and is a common method used by nearly all offenders while they prey on a victim's perceived vulnerabilities (DeBecker 1997). An attack will create a fight or flight response as well as a state of inertia (freeze) depending on a victim's awareness and self-defense skills. Successfully navigating the best defense to sudden, interpersonal human aggression requires an examination of psycho-physiological and biomechanical processes of a victim during times of critical stress.

Evolution of Self-defense

For many years, much debate has centered on the best models for achieving proficiency in armed and unarmed human conflicts. With a lack of similar and interchangeable defensive tactics and firearm programs for civilians, non-universal laws, and an ever-increasing field of commercial use of force systems, discerning the best defense against an attack by a violent offender is difficult (Kinnaird 2014).

Most unarmed self-defense techniques learned today have a historical lineage through war and military engagements over thousands of years (Grossman 2008). From our prehistoric ancestors to soldiers of the early twentieth century, fighting

tools and tactics were primitive and limited. Since the 1950s, however, martial arts techniques such as kung fu, karate, tae kwon do, jiu-jitsu, and aikido had gained significant momentum as staples in self-defense programming all over the world (Kinnaird 2014). Originating mostly from Asia and taught to those who lived or served in the war theaters of that region, the ability to fight largely with close-quarters orientations such as punches, kicks, and grappling techniques became popular in both sport and street combat (Siddle 1995).

From karate and kickboxing tournaments, law enforcement and military recruit academies to the lone vigilante on television and films who have made them popular, hand-to-hand fighting skills have taken on various forms over the years. Most recently, mixed martial arts techniques demonstrated in television and pay-per-view events such as the *Ultimate Fighting Championship* have been more narrowly transformed for close-quarters engagements and are widely renowned in military, law enforcement, and self-defense communities throughout the world (Kinnaird 2014).

According to research conducted by pioneers in contemporary personal protection, survival through effective self-defense has transitioned through yet another iteration. Blauer (2006) and Siddle (1995) explained that while traditional martial arts are great for fitness, discipline, focus, meditation, respect, and other valuable outlets, they do not always prepare a person for real street violence. Dogmatic self-defense examines mostly weapons and technique-based training: firearms, non-lethal devices, pressure points, wrist grabs, holds, and escapes (Miller 2011). If weapons are not available, a person is forced to use their body and fight in close quarters when they are attacked suddenly. While pain compliance techniques, for example, are effective, they are only effective in certain situations and circumstances (Blauer 2006).

Through studies of crimes against people, historical research into the functionality of warfare & combat, and along with new research that deconstructs the anatomy of a real attack, experts have made scientific correlations that highlight the validity and reliability of various self-defense systems. In doing so, a holistic model that accounts

for behaviors related to fear and performance enhancement creates awareness in how a person feels when threatened or attacked (Artwohl and Christensen 1997; Blauer 2006; Grossman 1996; Murray 2004; Siddle 1995).

Behavioral Defense

Emotional and psychological arousal comprises the first component of holistic self-defense. A psychomotor skill is generally defined as a body movement resulting from mental processes (Siddle 1995). Blauer (2006) explained that mental arousal is the first attack and therefore the mind navigates the body. In a stimulus-response environment, how you think determines how you feel and how you think and feel affects what you *do*. Because humans are attacked psychologically and emotionally before they are ever attacked physically, awareness through visualization and expectation are positive behavioral strategies for defense against the attack (Blauer 2006). This includes good confidence by looking people in the eye, being assertive through choice speech, rehearsing a violent attack ahead of time, and expecting to successfully defend yourself from it.

Using words or verbal defuses help to de-escalate a hostile situation (Meadows 2007). Because attackers will often talk and physically posture, all potential attacks can be observed by understanding the feelings behind the words and observing the postures that go with it. By offering compliant words to the aggressor or *redirecting* any words the attacker, the self-defense comes from an interruption in thinking patterns and provides time to escape or time to think of another strategy (Blauer 2006).

DeBecker (1997) explained that fear management is another tool for increased awareness and modern personal protection. Will, the power of indignation, tenacity, and primal instincts are natural and organic responses to survival that do not include rote memory and complicated training. Furthermore, observing the behavior and pre-contact cues of an aggressor will help establish an intuitive radar that can be accessed

immediately and into the future. This “gut instinct” is born out of continuous observance of stimuli and responses to stimuli and is the quickest and most accurate way for your brain and body to sense trouble. This sensation is derived from a total accumulation of past experience, knowledge, and what a person can anticipate happening and then use it to inform a choice under stress (DeBecker 1997).

Grossman (1996) explained that because interpersonal human aggression is a primary human phobia, the lack of awareness and acceptance of predatory and attacking behavior (denial) can create significant barriers to mental processing and slow the scenario down in a negative way. Artwohl and Christensen (1997) offered that organic fear happens when a person sees someone who is angry, when they aggressively encroach personal space, or when they make threats or use vulgar or abusive language. These translate into physical responses that lead to tactical choices of escape (flight) or defense (fight).

Physical Defense

Physiological arousal is the last component of understanding the biomechanics of confrontation and utilizing holistic self-defense strategies. When attacked in close-quarters, the situation is tense, evolving, and uncertain. Because the situation is out of control, researchers agree that the behavioral aspects of organic fear and awareness through training and experience will increase or decrease the physiological arousal in both perceiving the attack and using effective strategies to survive it (Blauer 2006).

Key points about how the body responds to stress from psychological and emotional precursors have been examined and reviewed through motor control and learning as core training rhetoric for the physiology of skill acquisition (Artwohl and Christensen 1997; Grossman 2008; Siddle 1995). This includes rudimentary skill classifications and taxonomies such as fine, complex, and gross motor skills. The body will have a neurophysiological response to fear and,

even if managed well, fear and survival instincts will kick in. This includes the adrenal gland “fight or flight” response to stress such as automatic pilot, diminished sounds, tunnel vision, increased heart rate, increased blood flow, dissociation, slow-motion time, memory loss, and short bursts of strength (Artwohl and Christensen 1997).

As stress during an attack increases, fine and complex motor skills decrease including dexterity and coordination (Siddle 1995). Retention of learned self-defense techniques that do not account for this psychomotor loss will not be palpable tools during a sudden, aggressive attack. When a stimulus such as a punch, grab, or shove is introduced quickly, it will by-pass the cognitive, muscle memory systems in the brain and will create a startle-flinch response. According to a research by Blauer (2006), the human body’s flinch to danger is a hard-wired, reliable, and protective bio-mechanic process. These survival behaviors work in concert with the body’s autonomic and somatic nervous systems whereby the limbic system of the brain takes over the forebrain and larger, cognitive processes.

During this close-quarters encounter, the body is left with gross motor functions and will instinctively shield the head and upper body with arms and hands while turning away from the danger simultaneously (Blauer 2006; Siddle 1995).

While all humans respond the same to being startled, their perception and awareness of danger (and subsequent fear management) is variable and both can compound the ability to defend and survive a close-quarters attack (DeBecker 1997). Therefore, the use of gross motor tactics such as slapping, pushing, shoving, biting, clawing, and the use of elbows and knees to strike the vulnerable areas of an attacker are now universally accepted and shaped into modern self-defense programming (Siddle 1995).

Conclusion

Defense against an attack requires a functional and realistic response for survival. Because the human body and mind are connected, a holistic self-defense program captures both. Rather than

relying on spiritual or mystical foundations and primitive fighting models, contemporary defensive tactics programs are now field tested and modified for dangerous environments and legal redress based upon how the mind and body respond to danger and violence. Effective self-defense is best examined through psychological and physical stressors on the body during a real or perceived attack. Because a critical event is often outside a person’s control, new research on the psychophysiology of confrontation illustrates how organic fear and stress affect human responses to interpersonal human aggression and, ultimately, the best tactics for preparation and defense during a close-quarters fight.

Synonyms

Killer; Self-defense; Situational awareness

Definition

Human, protective response to aggression and victimization through psychosocial and situational awareness.

Introduction

The role of predator and prey has long been studied through the animal kingdom of behavior, survival, and adaptation; however, only in recent decades has the concept been applied to human conditioning against predatory violence. Defending against a predator requires understanding the interactive dynamics of predator and prey and its intersection of violence and victimization. The psychological constructs of power, control, and the need to dominate another human being against permissive vulnerabilities when entering a human lion's den are all parts of a larger formula in examining the attractiveness of a victim and ultimately defending against a predator.

Victimization and Predatory Dynamics

Violence and victimization have traditionally been understood as random acts perpetrated upon unknowing people. Research into social and psychological dynamics is evolving, and recent findings have shifted from examining just cultural regression and active or passive *victims* to the *predator* and what they bring to the equation (Thomas 2013).

In examining deviant use of power, control, and domination of another human being, men have largely been identified as a predator. Inherent in predatory aggression are sociopathic and psychopathic tendencies evidenced by men where *survival* is their chief motivation. Wolman (1999) has explained that elation and depression originate from exaggerated feelings of strength and weakness. "Elation carries the message of power; depression is a psychological corollary of feeling weak and the angry at oneself for being weak" (Wolman 1999, p. 40). Suspending individual responsibility, they obliterate feelings of guilt and remove moral inhibitions, thereby launching violent or potentially violent behavior. The main attractiveness is power, and the predator will seek conditions where power and control are easily attained.

The Duluth Model or "Power and Control Wheel" exemplifies this unhealthy power through a circular and pervasive trait pattern demonstrated by male abusers of women (Pence and Paymar 1993). Not unlike a shark that circles a fish or a spider that spins a web and waits in the middle, the predator is often patient and pings his territory through continuous and observatory actions that box the victim in. The predator then wears the captive down until they are solely dependent upon them. This is an important distinction as run of the mill, rag-tag criminals do not pose the same strategies nor are they as effective in carrying out a crime (Thomas 2013). Because predators are largely ruled by impulses, they are incredibly sensitive to incentive structures and make informed decisions on whether an opportunity will pay off (Wolman 1999).

Victimization and Prey Dynamics

The concept of *victim* dates back to ancient civilizations and cultures originally, meaning to take the life of a person or animal to satisfy a deity (Karmen 1990). Today, victim and prey are used simultaneously as words that refer to different types of people: victims of domestic and sexual violence, hate crimes, workplace violence, and so forth. Victims are individuals

“who have suffered injury and harm by forces beyond their control and not related to their personal responsibility” (Karmen 1990, p. 5). Beyond just a cursory definition and sociocultural context, there are many different ways in which individuals can become victimized which requires an examination of behaviors and situations relative to the predator.

On a personal level, a victim of crime sustains the brutal reality of a deliberate violation of one human being by another (National Center for Victims of Crime 2004). Whether a murder, rape, robbery, or theft, an essential internal injury is the same, and the process, itself, induces a psychological trauma. The selection of prey by a predator is predicated on a reciprocity that exists between the “killer and the killed” (Meadows 2007). Modern theories are simply revised versions of earlier theories that studied victimization and produced victim classification systems. This includes higher-risk groups such as women, children, young adults, immigrants, minorities, elderly, and the disabled (Meadows 2007). These groups are often more prone to victimization given a diverse demographic field and large, male population. *Personal* factors such as immaturity, inexperience, lack of physical mobility, and mental illness are several variables that offer a direct line to predators, while *situational* factors including lifestyle, abuse of drugs and alcohol, spatial relationships, and associations with high-risk places further precipitate predatory victimization (McDevitt and Sgarzi 2003).

Cultural factors are another dynamic when examining typologies of victims who fall prey to interpersonal violence and human aggression. Galtung (1996) observed cultural trappings such as values, norms, and attitudes about race, gender, socioeconomic status, sexual orientation, and even child-rearing contribute to violence and victimization. A lack of familiarity with a different culture and rejection (or objectification) by a dominant population creates conditions where individuals and groups are specifically targeted. In these instances, dysfunctional families and perceptions of what is good or bad promote negative cultural values where survival and recognition are

necessary (Galtung 1996). In particular, African-American and Hispanic females from a low-income, inner city are highly prone to stalking behaviors and violent partners where those behaviors are observed as normal and necessary among families (Meadows 2007).

Putting It All Together

There are considerable exceptions and overlap when attempting to understand the best theory of victimization, and, historically, they are not intended to explain all types of predatory aggression or prey behaviors. With that in mind, a holistic model of self-defense against a predator is one that encompasses opportunity reduction strategies.

Crime prevention through environmental design is clearly articulated with the defensible space theory (Newman 1972). In it, effective defense requires detection strategies related to the physical environment. This includes understanding clearly defined territories, natural surveillance, and the general image of protection (Newman 1972). The most widely accepted adaptations from that foundation are the broken windows theory and crime triangle. Where individual people or structures like homes, buildings, and vehicles appear disorderly, it conveys a visual message that the associated culture and community are out of control and are thus attractive to predators (Kelling and Coles 1996). The use of adequate lighting, camera and other security systems, unobstructed windows, and employees trained in deterrence and safety provides signals to the predator. The non-enforcement of building codes, overlooking minor criminal conduct by law enforcement, and increasing locations that sell alcohol are additional factors that influence incivility and disorder in the eyes of a predator (Kelling and Coles 1996). Spatial relationships with other people also contribute to victimization where, ultimately, for crime to occur, there must be three variables present: a motivated offender, a susceptible target, and the absence of a capable guardian (Kelling and Coles 1996).

Conclusion

Defending against a predator in the world of interpersonal violence and human aggression requires a holistic understanding of psychological and social variables that create a high risk for victimization. Society has largely been trained that just learning physical defensive tactics is the best offensive mechanism for protection (Thomas 2013). A dynamic triad, however, that includes a study of the predator, the prey, and the environment in which both interact is a comprehensive and conclusive strategy for defense. It examines why the predator is attracted to potential victims and the high-risk places where these individuals have an exchange relationship.

Definition

Despite similarities in physical IPV perpetration rates among men and women, researchers have noted that the context of men's and women's violence may be very different. For example, men's IPV perpetration is more likely than women's to be driven by power and control motives, while women's violence is more likely to be motivated by self-defense. In fact, of the potential motivational differences for men's and women's physical violence, self-defense is among the most commonly cited.

Introduction

A relatively large body of research indicates that women perpetrate physical intimate partner violence (IPV) at rates comparable to men (e.g., Kaufman-Parks et al. 2017; Swan et al. 2008). Yet research also finds that women's violence usually occurs as a reaction to violence initiated by male partners, while men's violence is more often motivated by a need to control or exert power over partners (e.g., Langhinrichsen-Rohling et al. 2012). For example, in a study of

men and women court ordered to attend abuse treatment counseling, 83% of women, compared to 49% of men, reported their partners used violence first in the relationship (Hamberger and Guse 2002). Relatedly, in a sample of college undergraduates, frequency of victimization accounted for almost 50% of the variance in women's IPV perpetration, but accounted for only 12% of the variation among men (Cercone et al. 2005).

Gender-based disparities in motivations for IPV perpetration are especially likely to exist in clinical-based samples, where couples experience, on average, more severe acts of violence. Conversely, in community-based samples that typically exhibit less severe and less frequent acts of violence, men and women are equally likely to perpetrate IPV simply due to conflict and negative emotions (Cascardi and Vivian 1995). However, even among clinical-based samples, not all reactionary violence is alike. Rather, women may respond to their male partner's violence in order to protect themselves or their loved ones, as a result of heightened levels of fear, or as retaliation for previous victimization.

Violence as Self-Defense

The need to protect one's self or one's children is commonly cited in the literature as a motivation for female-perpetrated IPV (e.g., Flinck and Paavilainen 2010; Hamberger et al. 1997; Langhinrichsen-Rohling et al. 2012; Swan et al. 2008). For example, in a study of male and female court-referred perpetrators, Hamberger et al. (1997) found that women were more likely than men to report violence perpetration to protect themselves or to escape a situation in which their male partner was being violent. Likewise, in their meta-analytic review of women who use violence with intimate partners, Swan et al. (2008) noted that children whose mothers are battered face a significant increased risk of being abused as well. Thus, women may react violently toward male partners in order to protect their children from physical or sexual abuse.

Importantly, self-defense as a motive for female-perpetrated IPV may be defined either narrowly or broadly. As a narrow definition, and as legally defined, self-defense is limited to protecting one's physical self when there is an imminent threat of bodily harm. More broadly defined, self-defense may be viewed as a response to ongoing victimization through not only physical violence, but also emotional and verbal abuse, as well as experiences of coercion and intimidation (Dasgupta 2002). When considering self-defense more broadly, greater gender disparities in men's and women's motivations for violence are likely to emerge. As concluded in a meta-analytic review conducted by Swan et al. (2008), although women may be perpetrating as much or more physical violence as their male partners, their partners may be committing other types of abuse that are not always assessed, such as sexual abuse and coercive control. Thus, women may be responding violently to abuse other than physical IPV. Providing support for this notion, a study assessing violence in dating relationships among undergraduate students found that the two most common reasons for self-defensive aggression as reported by females were to stop emotional abuse or to stop a situation that was becoming emotionally abusive (Shorey et al. 2010). Likewise, in a study of couples receiving marital treatment, Cascardi and Vivian (1995) noted that wives reported that their husbands engaged in significantly more psychological abuse and coercion than they did during conflicts, leading to either spouse's use of physical violence. The authors concluded that, consistent with other research (Kernsmith 2005; Shorey et al. 2010), women may perceive psychological abuse as more personally damaging than partners' physical aggression. As a result, women may become violent to defend against a hurt ego or to protect their self-esteem.

Violence as Fear Response

In line with the notion that women may be responding with violence to IPV that is not necessarily physical in nature, women may strike out

preemptively when they sense impending violence from their partners. For instance, findings from a recent meta-analysis (Hamberger and Larsen 2015) suggested that female perpetrators were more highly victimized, injured, and fearful than male perpetrator in clinical samples; and more women than men felt intimidated by their partners' size and the potential injury they could cause during physical conflict. Similarly, in a study of men and women attending batterer intervention counseling, Kernsmith (2005) found that women were significantly more likely than men to report feeling scared, powerless, and weak when they perpetrated violence.

Women may also experience fear and react violently as a result, even if they have not been victimized by their current relationship partner. Rather, such fear may be the result of victimization in earlier life that is then carried over into future relationships. More specifically, prior research has found that women who perpetrate IPV report significantly more IPV victimization in prior relationships than men, as well as higher levels of sexual abuse as children and adults (Hamberger and Larsen 2015). Thus, even when violence is not objectively imminent, women may perceive threatening cues in the environment, whether due to prior victimization from their current relationship partner or others in earlier life, which indicate they are in physical danger. Once these cues are perceived, violence initiation may be seen as an appropriate strategy for preventing an impending attack or securing personal safety.

Violence as Retaliation

Within the literature on women's motivations for IPV perpetration, researchers have noted that it is oftentimes difficult to distinguish between self-defense and retaliation (e.g., Langhinrichsen-Rohling et al. 2012), whereby retaliation implies a violent act that extends beyond the need to protect one's self and also includes an aspect of retribution for something a partner has said or done. Distinguishing between these two concepts may be particularly important in assessing female-perpetrated IPV, as a number of researchers have

argued that rather than protecting themselves, women are oftentimes simply fighting back for the abuse they have endured (e.g., Hamberger and Larsen 2015). For example, among a sample of men and women attending batterer intervention counseling, Kernsmith (2005) found that women reported perpetrating IPV in response to their partner's prior abuse and were significantly more likely than men to report revenge and retaliation as their primary motives for engaging in such violence.

Women's retaliatory violence may not necessarily be a reaction to physical victimization either. In a recent study (Elmquist et al. 2014) of motivations for IPV among men and women arrested for domestic violence, retaliation was defined to include not only getting back at a partner for being hit first, but also punishing a partner for wrong behavior; retaliating for being emotionally hurt; to hurt a partner's feelings; because a partner provoked the respondent; and because a partner cheated. Moreover, of the seven potential motivations for IPV perpetration that were included in the study, significant gender differences existed only for reasons of expressing negative emotions and retaliation, with women endorsing both of these motives more often than men.

It has also been found that even when both men and women endorse retaliation as their primary motivation for engaging in IPV, the reason cited for their retaliation may be different. For example, Kernsmith (2005) found that women were significantly more likely than men to endorse "getting back at partner for emotional hurt" as an explanation for their violence. Similarly, Follingstad et al. (1991) found that retaliation toward a partner who had initiated violence was more likely to explain males' IPV perpetration, while retaliation for being emotionally hurt by a partner was more likely to explain female-perpetrated violence.

Conclusion

Women may be just as likely, if not more so, as men to perpetrate violence against intimate

partners. However, the context in which men and women engage in IPV perpetration is likely to exhibit a notable degree of variation. In particular, research indicates that men are significantly more likely to use violence to gain and maintain power and control in the relationship, while women's violence is often a reaction to that which is initiated by their male partners (Swan et al. 2008). Whether enacted to protect self and children, as a result of heightened levels of fear, or to retaliate against male partners' words and actions, women's violence can largely be understood as a defense strategy against partners' attacks, whether these attacks be real or perceived, and violent or nonviolent in nature.

Deferred Adaptations

Ross A. Thompson
University of California-Davis,
Davis, CA, USA

Synonyms

Non-transient ontogenetic adaptations

Definition

Deferred adaptations are behaviors or learning selected through evolution to facilitate later adult

functioning. They are often viewed as childhood preparations for adulthood. Examples of deferred adaptations are play (in which children simulate and rehearse adult roles and behavior), developing gender differences in behavior and motivation (which prepares for gendered adult responsibilities), and the young mind's orientation to novelty (which facilitates rapid learning). As these examples illustrate, deferred adaptations can have adaptive functions during the period in which they develop as well as in adulthood.

Introduction

Childhood and adolescence are typically viewed as a period in which the characteristics and skills necessary for adult functioning are prepared and rehearsed. This is true in evolutionary terms. Evolutionary adaptations have evolved to equip species with reliably developing characteristics that help to facilitate reproductive success, and many of these adaptations develop during the years of immaturity (Bjorklund 1997). This is important because, although the focus of evolutionary psychology is on how evolutionary adaptations function during adulthood when pair bonding, reproduction, and child rearing take place, adaptations also characterize childhood (see entry on ► [“Development of Adaptations”](#)). This makes the experiences of childhood significant for life-long development and the evolutionary adaptations influencing development. This is especially true of *deferred adaptations*, and this entry discusses deferred adaptations, provides several examples, and compares deferred adaptations with ontogenetic adaptations in childhood. In addition, examples of when deferred adaptations are also conditional adaptations, yielding a range of possible outcomes, are considered as an illustration of the flexibility or plasticity that can occur in evolutionary adaptations.

Evolutionary Adaptations in Childhood

There are two kinds of adaptations that emerge during childhood (see entry on ► [“Ontogenetic](#)

[Versus Deferred Adaptations”](#)). One kind, called *ontogenetic adaptations*, facilitates reproductive success by selecting for specific kinds of learning or behavior that facilitate development during a particular stage of growth, but have no necessary later significance (see entry on ► [“Ontogenetic Adaptations”](#)). An example is the umbilical cord and placenta that develop prenatally to support fetal development but are discarded when they are no longer needed after birth. Postnatal examples of ontogenetic adaptations include neonatal reflexes and the facial morphology of baby faces, each of which attract and keep caregivers nearby to provide nurturance, protection, and guidance. Ontogenetic adaptations are, in this sense, temporary or disposable adaptations.

Deferred adaptations, by contrast, have enduring significance because they are adaptive preparations for adult skills and characteristics. In some cases, these adaptations serve to promote adaptive functioning both when they are developing and in adulthood. In this respect, they are not temporary but have life-long significance.

Deferred Adaptations

Deferred adaptations are behaviors or learning selected through evolution to facilitate later adult functioning. However, these adaptations can also support children's adaptive functioning as they are developing. Children's play is often regarded as a deferred adaptation in which children simulate and rehearse adult roles and behavior, including adult work, parenting, and aggression. But children's play also facilitates early social development and integration into the peer group. The development of some behavioral and psychological differences between boys and girls can also be regarded as deferred adaptations to prepare children for the gendered roles they will assume as adults. Other likely deferred adaptations are the infant mind's orientation to novelty (from which rapid learning can occur), certain forms of innate or very early learning (including rapid early learning about gravity and physical causality), and the generally slow pace of early development in humans compared with other species. Each of

these adaptations promotes competent functioning in childhood but also prepare adult skills and competencies.

Whether behavior is interpreted as deriving from an ontogenetic adaptation or a deferred adaptation is quite important. Consider the development of infant-parent attachment (Thompson 2013a). On one hand, attachment could be viewed as an ontogenetic adaptation to help keep infants protected and nurtured by their parents (usually mothers) during their vulnerable early years. Viewed in this light, these attachments have no necessary long-term significance after children reach maturity. On the other hand, attachment could be viewed as a deferred adaptation that also prepares children for the close relationships they will depend on as adults. From this perspective, the strength or quality of these attachments could have enduring significance throughout adulthood.

Plasticity in Developmental Outcomes: Conditional Adaptations

Deferred adaptations sometimes result not in a single adaptive developmental outcome, but rather a range of possible outcomes, the choice of which depends on environmental conditions. This has the benefit of conferring flexibility or plasticity to these adaptations depending on the circumstances in which the individual lives. This illustrates a process called adaptive phenotypic plasticity: the selection for a range of behavioral outcomes depending on environmental conditions and other influences. This is a kind of deferred adaptation called a conditional adaptation (Boyce and Ellis 2005).

Consider again infant-parent attachment. Infants develop attachments to their mothers but they also vary in the security of those attachments: some become secure in their mother's care, others become more avoidant, others anxious. These variations in the security of attachment derive, in part, from differences in the quality of care. Securely-attached children tend to have responsive mothers, while those who are avoidant have mothers who are generally nonresponsive,

and anxiously attached children have mothers who are inconsistently responsive (Thompson 2013b). If attachment is interpreted as a deferred adaptation, then these variations also suggest that attachment is a conditional adaptation, in which the most adaptive attachment pattern that develops depends on the quality of care the child has received. In a sense, the adaptation commits the child to a particular developmental course only once relevant signals have been received from the environment – in this case, the quality of care the child receives.

The different patterns of attachment that result may, in turn, have longer-term significance for adult functioning. According to several theorists, these patterns of attachment evolved because they were adaptations to different amounts of maternal responsiveness that reflected differences in the safety and resources of the environment into which child had been born. In an environment of scarcity, for example, when mothers are unresponsive because danger is high and food is scarce, an avoidant pattern frees the child to seek support and assistance elsewhere (Belsky 2012; Chisholm 1999). That avoidant pattern may also, later in life, cause the adult to be cautious with others and sensitive to resources and stress. There is some supportive evidence for this view, although more research is needed (Ellis et al. 2009).

Conclusion

Evolutionary adaptations influence development throughout life. Deferred adaptations provide developing individuals with preparation for the capabilities and skills necessary for adult functioning, while usually also providing benefits during the period they are developing. When deferred adaptations are also conditional adaptations, they provide a range of possible behavioral outcomes that depend on environmental conditions and other influences. This provides developing persons with greater flexibility (or plasticity) in accommodating in necessary ways to the conditions in which they have been born.

There can be debate over whether certain developing capacities (such as infant-parent

attachment) constitute deferred adaptations or not, and this debate is important for understanding the potentially life-long significance of these early-developing capacities. As the catalogue of likely deferred adaptations (and ontogenetic adaptations) grows, understanding of the significance of early experience for life-long adaptive processes also grows.

Deindividuation

Jody A. Thompson
University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonyms

[Anonymity](#); [Behavior in groups](#); [Situational behavior](#)

Definition

Loss of individuality and a sense of anonymity that make individuals more likely to take part in antisocial behaviors.

Introduction

While an individual may display certain explicit attitudes, patterns of behavior, etc., when an individual holds a unique position within a group, a group can work successfully, and the ideals of the individual within the group may not show a significant shift as when they are alone. However, when an individual loses their sense of uniqueness

or identity within a group, deindividuation occurs. Deindividuation is the loss of individual accountability within a group setting.

Deindividuation and Antisocial Behavior

Stanisław Jerzy Lec once said, “No snowflake in an avalanche ever feels responsible.” Once deindividuation occurs, these individuals are much more likely to commit antisocial behaviors and not always feel responsible for their actions. History has shown time and again the way that deindividuation can influence people. Fascist movements held that the individual should submerge themselves into the group and that self-interests should be secondary to that of the interests of the group. One major example of this was the German Nazi Party. They were impressive in rebuilding their bedraggled nation. They were able to stand against the great powers of the world; however, their inner workings fell into a debauched society of shocking cruelty and evil that went well beyond what had been seen in other countries. Another example is that of the Ku Klux Klan. Members of this group would don hoods and robes, hiding their individual faces, and then commit violent acts on members of groups that they viewed as inferior. Diener et al. (1976) ran a study on stealing Halloween candy committed by trick-or-treaters. Some children were observed trick-or-treating alone, while others would go in groups. For this study, children that were randomly assigned to groups were set up so that one group could be easily identified and the other group had their identity remain hidden. Those in the identifiable group were asked their names and where they lived. The experimenter would repeat the names and addresses given to show they knew the children’s identity. Those in the anonymous group were asked nothing. These same principles applied to children that were tested alone. The experimenter then told the children that they were allowed to take one piece of candy and that the experimenter had to leave the room and go back to work. Children were monitored to observe how many pieces of candy each actually took

from a large bowl of candy. The results showed that alone and identifiable children stole extra candy less than 10% of the time. Anonymous and alone, as well as identifiable and in groups, stole extra candy roughly 21% of the time. Anonymous and in group children, however, stole extra candy almost 60% of the time. This study inarguably shows that anonymity in groups drastically increases antisocial behavior. The children that felt most accountable were the most unwilling to steal, while the children that had the least accountability stole well over half the time.

Reducing Deindividuation

The effects of deindividuation can be reduced. The best way of doing is to make individuals feel accountable for their actions. Taking away the anonymity of the individual within a group can easily alter their perceptions and behaviors. An example of this is from the Harper Lee’s novel *To Kill a Mockingbird* (1960). From pages 153–154, Lee describes a scene where a group is coming to the jailhouse to lynch Tom Robinson, an African-American falsely accused of a crime, and his lawyer, Atticus Finch, is there to stand between the mob and the jail. Scout, Atticus’s 8-year-old daughter, walks into the crowd and starts naming members and asking them personally why they are at the jail and what they intend to do to her father. Once the crowd shifted from a faceless group to a collection of individuals, they disseminated and no longer threatened violence. They reduced the anonymity and the effects of deindividuation dissolved. In his book, *The Lucifer Effect*, (2007) Philip Zimbardo brings up the idea of creating a better situation. He suggests that by celebrating those they break away from the crowd and retain their individuality, other persons will be less likely to accept the anonymity of a crowd.

Internet and Deindividuation

With the wide availability and use of the internet as a way of communication with others,

deindividuation is very common. While this form of deindividuation may not always take the form of physical groups, cyber groups can do a lot of harm. Hacking, identity theft, and cyber bullying have become very common online. Catching these individuals can be difficult in this arena; it makes attempts to reduce deindividuation extremely difficult as well.

Conclusion

Deindividuation is very powerful. When individuals lose their self-awareness and sense of accountability, negative behaviors tend to emerge. While group behavior can be highly effective, getting lost within a group can be very dangerous. Measures need to be taken to create better accountability and acceptance of personal responsibility, even when the individual plays only a small role in the overall process.

Denis Decatanzaro

Kristen Syme
Washington State University, Vancouver, WA,
USA

Introduction

Denys deCatanzaro is Professor of Psychology, Neuroscience, and Behavior at McMaster University. He received his Ph.D. from the University of British Columbia. His research interests and publications span the topics of reproductive toxicology, reproductive biology, neuroscience, and behavioral endocrinology. deCatanzaro developed the inclusive fitness model of suicide, which posits that suicide evolved to benefit genetic kin when an individual has low reproductive potential and is burdensome on their kin (1981, 1984, 1991, 1995).

Overview of Evolutionary Theoretical Research

In a series of papers published over the course of two decades, deCatanzaro outlined and tested a model of suicide that frames the act in a socio-biological perspective (1978, 1981, 1984, 1991, 1995). This model sees suicide as a means of increasing one's inclusive fitness when one has low reproductive potential and is imposing net costs of genetic kin, such as in the case of a debilitating illness. However, based on the evidence for the role of negative affect in precipitating suicidal ideation and suicidal behavior, deCatanzaro argued that emotion effectively acts as an interface between evolutionary catalysts (i.e., low reproductive potential and burdensomeness) and suicidal gestures (1995). Unlike alternative evolutionary models that focus on costly signaling and nonlethal suicidal behavior (e.g., the bargaining model, see Syme et al. 2016), the goal of suicidal behavior within the framework of the inclusive fitness model is death.

There is some support for the inclusive fitness of model from different areas of research including deCatanzaro's own investigations. Self-sacrifice through death is evidenced in a variety of species such as sterile castes of the order Hymenoptera for the purpose of colony defense (Preti 2007). Similarly, in *E. coli* self-sacrifice might function to limit the transmission of a bacteriophage to related organisms (Refardt et al. 2013). In Western, predominately white populations, the risk of suicide death tends to increase as a function of age, especially among males as reproductive potential decreases (Shah 2007). A survey administered by deCatanzaro (1995) found that measures of poor reproductive potential and low valuations of one's worth to their family correlated with suicidal ideation. In a test of the inclusive fitness model against 53 cultures in the ethnographic record, Syme et al. (2016) found that evidence for deCatanzaro's inclusive fitness model increased as a function of latitude. Thus, there was greater evidence for inclusive fitness model suicides in resource-scarce environments such as the Arctic where the provisioning of nonreproductive and infirm kin can be costly. Finally, according to Brown et al. (2009), low measures of health and low satisfaction in romantic relationships were associated self-destructive motivation among college students. In this same study, the researchers also found an inverse relationship between maternal age and self-destructive motivation, indicating that the reproductive value of kin might moderate the desire for suicide.

deCatanzaro (1995) attested that all instances of suicidal behavior are not necessarily adaptive, especially in the modern environment. Novel technology such as guns and cars, for instance, might create contexts where individuals with otherwise high reproductive potential are more susceptible to die by suicide, as the putative evolutionary mechanisms for suicide would not account for methods with such high lethality. Social learning might also factor into suicidal behavior as is evidenced by copy-cat suicides (1995).

deCatanzaro's more recent work focuses on the impact of endogenous and exogenous estrogens on reproduction in mice.

Conclusion

deCatanzaro's model of suicide is well supported by empirical evidence in some cases. A sense of burdensomeness is a risk factor for suicidal ideation, and in some environments, incurring costs on close kin likely facilitates suicide as is evidenced by specific cultural models of suicide in some Arctic cultures. Nevertheless, not all instances of suicidal behavior appear to fit under a single model.

Definition

Major depressive disorder (MDD) is a mood disorder characterized by either depressed mood or loss of interest nearly every day for at least 2 weeks. Five or more of the following symptoms must also co-occur for a diagnosis to be made: significant weight loss or weight gain;

insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of pleasure; feelings of worthlessness or excessive guilt; diminished ability to think and concentrate, indecisiveness; and recurrent thoughts of death and suicidal ideation (American Psychiatric Association 2013).

Introduction

Why are melancholic states of mind so common? Most people have the capacity to experience sadness, for example, after experiences of loss. Nonhuman mammals portray sadness-like behavior, suggesting low mood has a long evolutionary history. Further, depression is also a diagnosable disorder with remarkable costs to its sufferers. Typical symptoms of clinical depression are lack of motivation, sleeplessness, loss of appetite and sexual desire, loss of psychomotor functions, failure to concentrate, and suicidality. People with depression also tend to spend a lot of time ruminating; they brood about their symptoms and its consequences (Nolen-Hoeksema 1991). It is an evolutionary mystery why humans are prone to this condition. The evolutionary adaptationist approach has offered an original approach to depression: Do depression symptoms serve any evolutionary advantages?

The current chapter will review evolutionary perspectives as to why depression exists. Some of these postulate that depression itself is an evolved adaptation with specific functions. Others argue for depression being a side effect of other evolutionary processes, while others still view depression as a maladaptive condition that is maintained by mutations and mismatches.

Why Does Normal Sadness Exist at All?

Emotions are evolved psychological adaptations. Fear, sexual arousal, jealousy, and disgust exist for specific evolutionary reasons. Broadly speaking, emotions assign behavioral priorities, or motivation, to different fitness-related situations. Different behavior patterns are required

depending on whether an organism is responding to a threat or to a mate.

Unpleasant emotions like sadness might function as a human defense similar to vomiting and physical pain (Nesse 2012). However, we still do not know why sadness exists and what its evolutionary functions might be. The only thing that is clear is that understanding maladaptive extremes of sadness is likely to be improved by understanding their normal function.

Humans tend to have optimistic outlooks on themselves and the world, and it might be useful to downregulate these tendencies in some situations. For instance, happy people are impulsive and tend to think less deliberately about the consequences of their actions, and people in a negative mood also tend to produce more persuasive arguments on controversial topics compared to happy people (see Forgas 2013). Further, sadness might help us detach from significant others or valued objects (Nesse 2012). Results like these give us some hints toward particular advantages sadness might bring to specific situations.

Evolutionary Theories of Depression

Social Competition Hypothesis

The social competition hypothesis postulates that depression is an involuntary strategy that is elicited during hierarchical encounters (Price et al. 1994). The idea is that depression is an “involuntary defeat strategy” which is activated in humans after losing in competitive social struggles (Gilbert 1992). If this social struggle remains unsolved, this defeat strategy can become dysregulated and manifest itself as symptoms of major depressive disorder. This theory is partly based on observations of nonhuman animals, whereby depressive behaviors such as a stooped posture and a downturned facial gaze are observed after losing a battle for resources or mates (Price et al. 1994). The depressive behaviors hence serve as reliable signals of “I am no threat” and “I am out of action” (Gilbert 1992). The social competition hypothesis postulates that depression serves the same evolutionary function in humans. Depressed humans, hence, are predicted to accept their situation and to be viewed by others as

nonthreatening. This hypothesis also predicts that depression will effectively inhibit aggression from others and the depressive will decrease the chance of being ostracized from their group.

Behavioral Shutdown and the Resource Conservation Hypotheses

The behavioral shutdown hypothesis states that an individual should decrease its energy expenditure when under chronic stress or when the goals of an individual become unreachable (Henriques 2000; Nesse 2012). These models of depression therefore predict that depression is activated when continued effort is futile or dangerous (Nesse 2012). For example, when obstacles to goals become impossible to manage, low mood is activated in order to encourage disengagement and reassessment of goals. Again, if the individual fails to give up the goal (e.g., by being overly ambitious or stubborn), the response can become dysregulated and manifest itself as depressive disorder.

Analytical Rumination Hypothesis

The analytical rumination hypothesis is a radical and comprehensive adaptive explanation of depression. According to the analytical rumination hypothesis, the most important aspect of depression is depressive rumination, which is considered to be an analytical tool designed to solve complex fitness-related problems (Andrews and Thomson 2009). Ruminative responses typically focus inward on feelings of distress rather than taking action to feel better, and it is a way of responding to distress by repetitively and passively focusing on the fact that one is depressed, the symptoms of being depressed, and the causes and consequences of having these symptoms (Nolen-Hoeksema 1991).

Other symptoms of depression are secondary and interpreted as orchestrated mechanisms designed to reserve limited cognitive resources for analytical rumination. The analytical rumination hypothesis states that a depressive episode is triggered by severe complex problems that require sustained analysis. Anhedonia removes rewarding emotions from previously pleasurable activities and thoughts, thus freeing up valuable cognitive resources for rumination. Various

psychomotor changes like loss of appetite and desire for social isolation further reduce exposure to distracting stimuli. In essence, depressive episodes are tailored to prioritize attention and resources toward the goal of solving the triggering problem, over more immediate short-term goals. The most central prediction of the analytical rumination hypothesis is that encouragement and facilitation of rumination should lead to shorter depressive episodes, and, inversely, cessation of rumination should have harmful effects in the long term.

Bargaining Hypothesis

The bargaining hypothesis postulates that depression serves the function of eliciting help from others (Hagen 2003; Watson and Andrews 2002). Depression is uncontrollable by the depressive. This is crucial from the bargaining perspective because it forces other people to act. Hence, depression functions as a worker's strike: I am unable to do anything, and this will result in me involuntarily withholding any resources that I could share, before I receive the help I need. A key prediction from the bargaining hypothesis is therefore that genuine help from people important to the depressive (e.g., a husband, family, or a close friend) will relieve the depressive symptoms.

Social Risk Hypothesis

According to the social risk hypothesis, mild depressive symptoms reduce social risks such as exclusion from social groups (Allen and Badcock 2003). Under the social risk hypothesis, depression serves the function of making the depressive hypersensitive to potential social (but not nonsocial) losses and hence becomes a more accurate social perceiver. This is based on the theoretical argument that social organisms should be able to calculate their own social value and social burden and incorporate appropriate behavioral strategies. The key part of human depression is that it works as an emotional mediator of behavior that reduces social risks when someone view their burden/value ratio to be unfavorable. A prediction from the social risk hypothesis is that perceptions and actual threats of social exclusion should lead to

depressed affect. A key prediction is that depression will actually help; depression should reduce the risk for social exclusion. Another interesting prediction from the social risk hypothesis is that individual humans who are unable to calculate their social value and burden should not have the capacity for depression (Allen and Badcock 2003).

Badcock et al. (2017) have elaborated their social risk view of depression based on a perspective on the brain as a prediction machine. People have models of the world, and brains are designed by evolution to reduce the errors the models make. The point is to reduce uncertainty and prediction errors. Under this view, normal low mood is an “adaptive prior,” meaning that the depressed person avoids interpersonal interactions that ancestrally were associated with aversive social outcomes. The depressed brain predicts aversive outcomes and therefore behaves in a risk-averse manner. Under the social risk hypothesis, clinical depression is likely to be the dysregulation of these adaptive processes (Allen and Badcock 2003).

Infection Prevention: Pathogen Host Defense Hypothesis

Pathogens are dangerous to humans. The evolutionarily ancient battle between pathogens and humans has resulted in a vastly complex immune system. Raison and Miller (2013) observed that many of the risk genes associated with depression are also involved in inflammatory responses. Hence, their main claim is that alleles associated with depression are maintained in the human genome because they help fight off attacks from pathogens. Depression is a by-product of this process. Raison and Miller (2013) postulate that the benefits of the immunological response outweighs the costs of depression.

A key prediction from the pathogen host defense hypothesis is that depression should be associated with increased inflammation and that inflammation is associated with increased depression. Further, allelic risk variants for depression should increase survival during infection. A good test of one of its predictions would be to look at depressed and nondepressed infected individuals

and see whether the depressed people are on average less likely to die from an infection.

The link between the immune system and psychological symptoms of depression appears to be robust (Miller and Raison 2016). And some of the predictions of the pathogen host defense hypothesis have been supported, for example, that psychological symptoms of depression are associated with greater immune activation (Stieglitz et al. 2015).

Sex Differences in Depression

It is a robust finding in psychopathology that women are affected by depression twice as often as men (Nolen-Hoeksema et al. 2003). Studies show that the sex difference in depression peaks in adolescence and declines and remains stable in adulthood (Salk et al. 2017). That the symptoms have their onset during sexual maturation suggests that sex-differentiated adaptations might play important roles in depression.

A variety of proximate factors are assumed to play a part in the sex difference in depression, including brain chemistry and genetics, dysfunctional ways of thinking, abusive relationships, financial issues, as well as cultural and social roles for men and women (Clarke 2006). Women’s tendency to ruminate more than men in response to depressive moods is also considered an important factor when explaining sex differences in depression (Nolen-Hoeksema et al. 2003).

The adaptationist theories of depression propose some ideas on why the sex difference exists. The social competition hypothesis views the sex difference in depression as a by-product of modern societies and not a functional one (Price et al. 1994). The bargaining hypothesis views bargaining strategies as more important for females because it is a relatively safe strategy, especially because lower upper-body strength hinders females from using anger instead of depression (E. H. Hagen and Rosenström 2016). The analytical rumination hypothesis proposes that females have been under greater selection pressures to spend more cognitive resources on avoiding social strains.

Problems with Adaptive Theories of Depression

Psychological adaptations are complex evolved structures that have been designed by selection to solve particular adaptive problems. In order for a trait to be considered a psychological adaptation, the trait must (1) show evidence of good design, (2) have appropriate activation, and (3) lack heritable variation (Nettle 2004). Depression does not meet any of these criteria.

Most humans experience fear in situations that are appropriate (e.g., while being threatened by an aggressive, formidable, and dominant male). If depression is adaptive in similar ways as fear presumably is, we would expect most people to become depressed in relevant situations. This is not the case. Depressive episodes do seem to be triggered by negative life events, although notably this is predominantly true of the first few episodes. Thereafter there is no obvious precipitating event. Further, the effect of negative life events is typically mediated by genetic factors (Kendler and Prescott 2006). And most people who experience similar life stress do not become depressed, and hence depression seems unlikely to be part of the evolved, universal human repertoire. Another problem is that depression does not show reliable evidence of “good design.” For example, the best predictor of a depressive episode is *past* depressive episodes. In other words, if depression is an evolved adaptation to solve social problems, for example, it does not seem to be effective at solving it because depression keeps recurring.

The bargaining hypothesis and analytical rumination hypothesis share the bold claim that symptoms of major depressive disorder often are the manifestations of underlying evolved adaptations rather than being the result of dysregulated processes.

A theoretical challenge for the analytical rumination hypothesis in particular is the efficacy of meta-cognitive therapy (MCT). MCT is based on theoretical underpinnings that consider rumination to be a harmful driving force of depression, which maintains and prolongs depressive episodes and symptoms. MCT consists of techniques designed to cessate rumination and dispel positive

beliefs about rumination (such as “I need to ruminate on my problems in order to find solutions”). If anhedonia and psychomotor changes and other symptoms of depression function to maintain rumination, targeted cessation of rumination should not relieve symptoms of depression, especially when patients are measured at 6 months follow-up (Hagen et al. 2017).

We do not know why the robust sex difference in depression exists either, and the adaptive theories do not give this problem the attention it deserves. The adaptationist approaches also typically fail to explain why male levels of depression vary so much across cultures, which might in itself be an important reason why we see a sex difference (Schmitt 2014). Nevertheless, there are many known sex differences in normal social cognition whereby females portray superior abilities in empathy, language, and emotional expression. Hence, evolved cognitive sex differences might serve as the basis for understanding sex differences in maladaptive pathology also (Martel 2013).

The Problem of Heterogeneity

Depression is a complex disorder. It is the DSM and ICD that bring together the cluster of symptoms that make up major depressive disorder. But depressed patients are remarkably heterogeneous: Some sleep less, some more. Some are suicidal, some are not. Some have strong feelings of guilt but not worthlessness and so on. So when researchers are looking into “depression” as a phenomenon, they are by definition looking at clusters of symptoms. An adaptationist look at depression needs, therefore, to know what symptoms are relevant for the proposed function. The ARH is one of the adaptationist approaches that addresses most different aspects of depression in general.

The Problem of Genetic Variation

Genetic variants that contribute to the design of psychological adaptations will over time spread throughout the population and become part of the universal genetic design within the species. For this reason, evolutionary psychologists assume that the heritability of evolved traits should approach zero. A finding across twin

studies on depression is that major depression is estimated to have a heritability of 31–42% (Sullivan et al. 2000). This variance is a challenge for adaptationist hypotheses of depression.

Three different evolutionary forces are responsible for maintaining genetic differences over time (Zietsch et al. 2015). The first is *mutation-selection balance*, whereby selection is a balance between new deleterious mutations that arise in the population and their eventual removal by purifying selection. The second is *neutral mutation drift*. Here genetic mutations are completely, or nearly completely, neutral to selection so their fixation or removal in the genome is caused by chance. The third is balancing selection, which is a group of different processes whereby genetic variance is actively maintained by selection because their relative fitness depends on the genetic and environmental context (Zietsch et al. 2015). Adaptationist hypotheses often do not address the crucial problem of why risk alleles for depression persist at all, or they assume that balancing selection adaptively maintains depression risk or that the alleles were neutral during human evolution and is not anymore.

Can Mutation Selection Balancing Explain Why Depression Alleles Are Maintained in the Population?

If depression is an evolved psychological adaptation, we would expect that the genetic variance underlying it is adaptively maintained by selection. That is, some force of balancing selection keeps the genetic variance in place. However, this is unlikely to be the case, because traits being maintained by balancing selection are actually very rare in nature. For example, with frequency-dependent selection (a form of balancing selection), the genetic variance is often caused by few genes with large effect sizes (Zietsch et al. 2015). Genetic psychiatry would have found these by now (Keller and Miller 2006).

A more plausible solution is that the genetic variance underlying depression is maladaptive. There is a constant influx of new deleterious mutations into the human genome. Some of these mutations are catastrophic and are removed quickly from the population (e.g., leading to

nonviable fetus or to early death). However, many have only a very slight negative impact on fitness. Therefore, by definition, it takes a while for selection to remove those harmful mutations. About half of human genes are involved in the construction and maintenance of the human nervous system. The human brain therefore has a large “mutational target size,” meaning that the many functions of the human brain are vulnerable to mutations (Keller and Miller 2006).

Consistent with the mutation-balancing selection view of major depression, the risk for developing depression is greater on islands where inbreeding rates are higher (Rudan et al. 2003). Inbreeding is harmful because deleterious recessive alleles are more likely to express themselves in offspring when both parents are genetically similar. If the prevalence of a trait increases as the degree of inbreeding increases, it suggests that the trait is caused by mutations and is not an evolutionary adaptation.

The Future of Evolutionary Psychopathology of Depression

All of the adaptive theories of depression are testable. They sometimes overlap in predictions and sometimes directly contradict each other. This is not a problem in itself because low mood and depression might have several functions. There is also some reason to consider several subtypes of depression, which may be an umbrella term for several mood pathologies. The greater problem is that the hypotheses are rarely tested. Rigorous attempts at actually falsifying and comparing all of the hypotheses together will be an important focus in the future.

Another key part in the future of the evolutionary psychology of depression is to develop high-resolution understanding of the evolved architecture responsible for low mood in order to understand the environmental contexts that activate vulnerabilities for depression and, further, to combine that knowledge with the usage of evolutionary-genetic frameworks in order to understand why the risk alleles for depression persist in the population and what happens when

the evolved architecture is disrupted. Evolutionary mismatches such as post-industrialization diets, lack of sunlight exposure, and sleep deprivation (Hidaka 2012), economic inequalities, and the life history strategies of individuals (Giudice 2014) are important fields for empirical development within the field. Evolutionary psychopathologists will also need to pay attention to developments within evolutionary behavioral genetics (Zietsch et al. 2015) and modern psychiatric genetics. Finally, the functional aspects of empirically supported therapeutic interventions that discontinue maintaining and possibly maladaptive coping behaviors need to receive more attention by evolutionary psychopathologists.

Conclusion

The counterintuitive nature of adaptationism used to test seemingly maladaptive traits, and suggesting possible functions for them, provides science with both original and testable hypotheses. However, none of the evolutionarily theories on depression have really influenced psychiatric or clinical psychological practice or mainstream theorizing about depression. This is in stark contrast to anxiety treatment where the functional understanding to fear informed most anxiety therapists understanding of irrational and maladaptive levels of aversive activation and maladaptive safety behaviors.

A current major discussion within the evolutionary psychology of depression is whether rumination is adaptive or maladaptive (Kennair et al. 2017). Paul Andrews and colleagues are developing specific measures to study the benefits of rumination, while other groups are studying the role of specific types of rumination for depression. Currently the evidence for the beneficial effects of discontinuing rumination outweighs evidence in favor of promoting rumination, and there are reasons to fear detrimental patient effects of increasing rumination. It is too early to conclude anything about any evolved problem-solving function of rumination, but no matter what future research will show, this is an important new development within evolutionary clinical psychology.

After being primarily a theoretical discipline for many years, the evolutionary psychopathology of depression is increasingly becoming an empirical science while providing important synthesizing theoretical frameworks. Our hope is that the field will ultimately benefit suffering patients.

Depression (Paul Gilbert)

Shane Kavanaugh
Kavanaugh Counseling and Consulting, LLC,
Ames, IA, USA
Compass Tree Counseling, Ames, IA, USA

Synonyms

Clinical depression; Major depression

Definition

“A common mental disorder characterized by persistent sadness and loss of interest in activities that you normally enjoy, accompanied by an inability to carry out daily activities, for at least two weeks” (World Health Organization 2019).

Introduction

Professor and clinical psychologist Paul Gilbert utilizes an evolutionary approach toward

the study of depression through social rank theory (SRT). This model views depression in terms of adaptive and maladaptive functions. In the context of social conflict, depression functions to tone down a subordinate's positive affect, accept defeat/loss (i.e., not meeting one's goals), and submit to the dominant and to signal to the dominant that the subordinate is not a threat (Price 1972). This process could be seen as adaptive, if it allowed individuals to disengage from negative environments and seek new sources of support (Gilbert 1992; Gilbert and Bailey 2014). Instead, depression blocks these adaptive responses, leaving the stress system in a prolonged state of arousal and the depressed person feeling demobilized (Gilbert 2000b).

Toning Down of Positive Affect

Pathways to the toning down of positive affect are explained through the arrested defenses model (Gilbert 1992, 2001). This model states that the body's defense system (e.g., fight or flight) in response to stress or perceived threats can become blocked. For example, one may feel a heightened urge to escape but feel trapped or feel anger but suppress negative expression of emotions. This pattern of arousal and blocking of defenses can become chronic, which can lead to the toning down of positive affect. Indeed, depression has been associated with feelings of entrapment (Gilbert et al. 2004) and suppressed anger (Allan and Gilbert 2002).

Defeat/Loss

An early study by Gilbert and Allan (1998) found that subjective reports of defeat were more predictive of depression than hopelessness. Moreover, subjective defeat has also been strongly linked to experiences of anhedonia (i.e., loss of pleasure) and feelings of inferiority (Gilbert et al. 2002). This component of SRT highlights the ruminative aspect of depression wherein individuals may harass themselves

repeatedly by their own negative self-appraisals (Gilbert 2004; Gilbert and Irons 2005).

Submissive Behavior

Submissive behavior is typically associated with perceived lower social rank and can involve inhibition of one's negative emotions, lack of self-advocacy or assertiveness, and denial of one's own feelings to appease others (Gilbert and Allan 1994). These subordinate behaviors and self-perceptions may perpetuate heightened physiological responses to stress (Gilbert and Allan 1998; Gilbert and McGuire 1998).

Conclusion

In sum, depression emerges due to the chronic activation of the defense systems in response to stressors, which results in a toning down of positive affect. Particularly when people see themselves as inferior, feel trapped, or suppress their own negative emotions, depression can follow.

Depression (Randolph Nesse)

Brittany Lorentz
University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonyms

Hopelessness; Melancholy; Misery; Sadness

Definition

A mood causing feeling of severe sadness, loss of interest in desirable activities, and inhibiting the way one may think or act.

Introduction

As defined in evolutionary psychology, humans have evolved mechanisms that help to defend themselves against disease and/or various defects, which for the sake of this entry is narrowed to psychological and/or physical defects within the body. Human bodies oftentimes have ways of protecting themselves which are viewed as beneficial. These can be things such as fighting a disease by inducing vomiting, whereas some defects have no advantage, such as seizures. Physiologically speaking, it is proactive to correct a defect within the body; however, interfering in such matters by utilizing a defense mechanism has shown to be destructive (Nesse 2000).

Depression (Randolph Nesse)

Depression symptoms have been shown to have been aroused by various traumatic stimuli when adapting to particular situations. Within the same subject, each depressive episode has shown various symptoms (Keller and Nesse 2006). Researchers have hypothesized that our bodies use different depressive symptoms as an adaptive condition to cope with, oftentimes, severely difficult life situations. The question then must be asked: Is depression an evolved adaptation to the issues we cannot or have difficulties facing? According to Randy Nesse, an adult depressive episode is an attempt at adaptation that has failed due to either help not being available or the feeling as though one cannot ask for help (Nesse 2000). However, Nesse (2000) also points out that when one has experienced endogenous depression for a third and fourth time, it could be that depression may not be a defensive mechanism at all. Additionally, Nesse (2000) also inputted that by applying natural selection, we can begin to see

difficulty in explaining mood disorders as adaptive response is difficult to do as natural selection does not shape diseases, but that it is the reason for an individual's body to be left to vulnerabilities that result in diseases (Nesse 2006). This has led Nesse to questions of why natural selection did not develop the body to be more "resilient"; "why do we have wisdom teeth and an appendix?" and "Why do so many people experience debilitating episodes of depression?" (Nesse 2006). The question now however has evolved to this: "How does depression arise? Is depression a sudden onset like a stroke or cancer due to a malfunction or is it like pain or a fever in response of protection?" (Nesse 2006). If looking at depression offhand without background research, the answer is clear; depression comes from a defect within the body (Nesse 2006). When looking at depression without background research, the answer seems apparent; depression comes from a defect within the body (Nesse 2006).

However, another outlook we can have is that depression does not necessarily have to be a disadvantage. Depression can offer a particular advantage. For instance, let us imagine that our subject is experiencing a time of loss. By providing motivation to regain a sense of fulfillment to fill the void of loss or by directly replacing the loss, the subject learns to avoid similar situations, they learn ways to protect oneself or others and they also learn how to prevent similar situations (Nesse 2006). Additionally, depression can another way of a subject calling out for help by showing signs of low mood or even breaking down and crying in front of peers. Based on the perceptions of depression, both socially and in one-on-one situations, researchers can see how depression influences how subjects seek treatment and/or help. Looking at distinctions between psychologists and psychiatrists on how depression is defined, we see that psychologists will depict depression as "habits of negative thinking, or social factors," whereas psychiatrists see depression as "a brain disease" (Nesse and Ellsworth 2009). Therefore, individuals may either seek psychotherapy to discover some sort of understanding in what they're feeling, or they

may possibly try seeking medications to balance their mood.

Conclusion

All in all, there are consistant psychological theories over the evolved mechanism of depression and it is necessary to continue further research to investigate emotions and how they may be adaptive responses that have branched off of natural selection.

Depth Perception

Olga Lazareva

Drake University, Des Moines, IA, USA

Definition

Depth perception is a process of recovering distances to and between objects from a two-dimensional retinal projection or from a two-dimensional image depicting a three-dimensional scene.

Introduction

Depth perception is a classic case of an ill-defined problem in vision: In principle, an infinite number of three-dimensional configurations can produce the same two-dimensional retinal projection (Fig. 1; Lowe 1985; Marr 1982; Palmer 1999). To cope with this “inverse optics” problem, human visual system makes a number of assumptions about the likely arrangement of 3D objects given a specific 2D input (e.g., that the occluding object is usually located closer to an observer than the occluded object). These assumptions, together with information contained in retinal projection (or projections) are then used by visual system to recover position of the objects in depth.

Depth perception cues can be classified as binocular (requiring a comparison of retinal input from both eyes) or monocular (available from a retinal projection of a single eye). Furthermore, they can be dynamic (requiring movement of an observer or an image) or static (available in absence of any motion). Finally, depth perception cues can be ocular (based on the mechanics of the eye) or optical (based on the information obtained from retinal projection). Table 1 provides these classifications for several important depth cues. The relative importance of different depth cues for evaluating depth perception depends on a species, although experimental evidence in many cases is either mixed or incomplete.

Depth Perception, Fig. 1 An illustration of ambiguous nature of depth perception. A two-dimensional projection of a straight line on a retina could be produced by a straight line in a three-dimensional environment, or by an infinite number of other configurations aligned to produce the same two-dimensional projection

Ocular Depth Cues: Accommodation

Vertebrate eye can maintain a clear view of an object through the process of *accommodation* that involves changing either the shape of the lens (mammals, birds, and reptiles) or the distance between lens and retina (fish and amphibians). Correspondingly, information about tension of the muscles controlling these changes can be used to derive distance to the object in focus. This cue is unavailable in compound eyes with fixed-focus optics.

Although in humans this cue is used only at close distances, it is a crucial source of depth information in the African chameleon. When chameleon prepares to strike its prey, the distance of the tongue flick is determined exclusively by information obtained from accommodation (Harkness 1977). The limited use of accommodation for depth perception at close distances has also been documented in many other vertebrate species. For example, under monocular conditions toads can use accommodation cues to judge distance to the prey (Collett 1977; see a review by Land 2015). Similar mechanics exist in the single-chambered eyes of cephalopods, but whether these animals use accommodation cues to recover depth information is currently unknown.

Binocular Depth Cues: Binocular Disparity

See ► “Binocular Disparity.”

Depth Perception, Table 1 Classification of classic depth cues (see text for more details) (After Palmer (1999))

Depth cue	Ocular or optical?	Binocular or monocular?	Static or dynamic?
Accommodation	Ocular	Monocular	Static
Binocular disparity	Optical	Binocular	Static
Motion parallax	Optical	Monocular	Dynamic
Linear perspective	Optical	Monocular	Static
Texture gradient	Optical	Monocular	Static
Occlusion (interposition)	Optical	Monocular	Static

Dynamic Monocular Depth Cues: Motion Parallax

See ► [“Motion Parallax.”](#)

Static Monocular Depth Cues: Pictorial Depth Cues

Even in the absence of binocular information or motion cues, human observers are able to perceive depth in two-dimensional photographs and paintings by using cues such as occlusion, shading, or linear perspective. Despite their name, pictorial depth cues are not confined to pictures of the three-dimensional world: A person who keeps their head perfectly still and one eye closed would still be able to perceive depth in their surrounding environment (Palmer 1999). Moreover, under certain circumstances pictorial depth cues can override depth information provided by binocular disparity (e.g., when using pseudoscope; see Palmer 1999, for more details) indicating their powerful role in depth perception.

More than a dozen of different pictorial depth cues have been described for human vision. For example, the size of elements in naturally occurring textures, such as pebbles on a beach, can be used to judge the distance to the different parts of texture because this size decreases with the distance (Fig. 2; *texture gradient*). Relatedly, larger objects are perceived to be closer to the observer than smaller objects (*relative size*). Because parallel lines in a three-dimensional environment project on a two-dimensional retinal image as lines converging toward a single point on a horizon, such converging lines can be used to induce

perception of depth in a two-dimensional image (*linear perspective*). The position of the objects relative to horizon also induces perception of depth such that objects located closer to the horizon line are perceived to be farther away from the observer (*position relative to horizon*). Objects that partially block another object are perceived as being closer to the observer (*occlusion* or *interposition*; see ► [“Occlusion”](#)). Finally, *shadows* cast by the objects also induce strong perception of depth in a two-dimensional image. In humans, the ability to use these cues for ordering objects in depth develops during first year of life (Kavšek et al. 2012).

Only a few experiments explored the presence of pictorial depth cues in nonhuman animals. Horses, baboons, pigtailed macaques, and chimpanzees have been shown to use linear perspective cues for estimating depth (Barbet and Fagot 2007; Gunderson et al. 1993; Imura et al. 2008; Timney and Keil 1996). The ability to use shading cues to extract three-dimensional information about objects has been demonstrated for chimpanzees and starlings (Cook et al. 2012; Imura and Tomonaga 2003; Qadri et al. 2014). Pigtailed macaques also use relative size for ordering objects in depth (Gunderson et al. 1993).

Although multiple studies have explored the use of monocular depth perception cues in pigeons, their results have been mixed. On one hand, pigeons appear to be unaffected by linear perspective cues (Cerella 1977; Nagasaka et al. 2007); on the other, they are sensitive to the Ponzo illusion which is presumably mediated by linear perspective (Fujita et al. 1991). Multiple studies have demonstrated that pigeons appear not to recognize occluded objects in two-dimensional

D

Depth Perception, Fig. 2 An illustration of classical monocular depth perception cues. A perception of depth can be induced by a systematic change in the size of texture elements (texture gradient); a larger size of object located nearby in comparison to more distant objects (relative size); a presence of parallel lines converging on a single

point (linear perspective); a relative distance to the horizon line (position relative to horizon); a blocking of a more distant object by an object located closer to an observer (occlusion); or by presence of shadows and/or variations in shading of a surface of an object (shadows and shading)

displays (Sekuler et al. 1996; Ushitani and Fujita 2005), possibly because of the failure to separate an object from an occluder (DiPietro et al. 2002; Lazareva et al. 2007). Yet, Cavoto and Cook (2006) reported that pigeons can use occlusion, together with relative size and relative density, to extract information about relative location of the objects in depth. Recent research has also demonstrated that pigeons can recover shape of the object from information provided by its shading, again suggesting the use of monocular depth perception cues similar to that of primates (Cook et al. 2012). It is likely that some of the disparate results can be attributed to different stimulus material or different training approaches; more research is needed to address this possibility.

Among the invertebrates, cuttlefish has been shown to respond to changes in texture density

(Josef et al. 2014) and to shading cues (Zylinski et al. 2016), but the use of other monocular depth cues in single-chambered eyes of invertebrates remains largely unexplored.

Unique Static Monocular Cues: Retinal Defocus and Retinal Blur

As an observer's eye focuses on a specific point in the environment, the focused object falls on the fovea but the parts of the visual environment away from fixation point become gradually blurred. This retinal blur can then serve as another static monocular depth cue in human vision, although it is mostly useful for recovering depth information at very close distances (Vishwanath and Blaser 2010).

In contrast to human eyes that experience retinal blur temporarily as a side effect of focusing, two invertebrate species appear to have permanent retinal defocus in a large portion of their retina. The rear portion of retina in young oval squid has a bulge, or a retinal bump, that results in permanently myopic image due to closer distance to the lens in comparison to the rest of retina. The squids use this cue in conjunction with a bobbing movement of their head to bring the potential prey into a focus (Chung and Marshall 2014). Interestingly, the retinal bulge disappears with age allowing sharp vision across the entire retina in the older animals.

Jumping spiders also use retinal defocus for evaluating distance to the objects. These animals possess several pairs of individual single-chambered eyes serving different functions (Harland et al. 2012). The large principal eyes have a complex, four-layer retina, with two deepest layers containing high concentration of photoreceptors sensitive to green light. However, this light is only focused on the deepest, fourth layer, with the third layer receiving defocused images; the contrast between the focused image in fourth layer and defocused image in third layer can then be used as a depth cue. Consistent with this hypothesis, spiders underestimated a distance to a prey under pure red light and overestimated it under pure green light (Nagata et al. 2012). Water-beetle larvae have been hypothesized to use similar depth cue although direct experimental evidence supporting this idea is currently unavailable (Stowasser and Buschbeck 2014).

Unique Static Monocular Depth Cues: Retinal Elevation with Respect to the Ground

Many vertebrates including humans use retinal elevation, or the distance from the retina to the ground, to adjust their estimate of the distance from the observer to the object. In many species, however, retinal elevation is used as a reference frame for evaluating distance produced by other cues rather than on its own. For example, visual system of frogs estimates the distance to the prey

under the assumption that its eyes are located approximately 3 cm above the ground; if this assumption is no longer correct because the frog has artificially been lifted above the ground, then it underestimates the distance to the prey (Collett and Udin 1988). Similarly, human visual system takes into account retinal elevation when evaluating the distance to the object (Ooi et al. 2001), although some argue that postural cues rather than retinal elevation per se plays more important role in determining eye height (Leyrer et al. 2015).

In contrast, a fiddler crab (*Uca vomeris*) apparently relies exclusively on retinal elevation to evaluate a distance between an intruder and its own burrow. Fiddler crabs possess two compound eyes that sit on top of the long vertical stalks; as is typical for compound eyes, they provide a relatively poor resolution for their size. In a series of elegant experiments, Hemmi and Zell (2003) have shown that fiddler crabs keep tabs on the location of the burrow by positioning themselves so that its entrance always falls on the same horizontal position on crab's retina irrespective of whether this entrance is actually visible. The vertical location of the projection then provides the crab with information about the distance to the burrow; the farther away the burrow is, the closer its projection to the horizon. Whether other species with compound eyes also use similar cues to evaluate distance is currently unknown.

Conclusion

Human observers use multiple ocular and optical cues to accurately recover distance to the objects in the three-dimensional environment from the two-dimensional retinal projection. Some of these cues, such as motion parallax, appear to be used widely across many different species with extremely different anatomical eye structures while others seem to be limited to specific eye type (e.g., accommodation in single-chambered eyes) or specific eye arrangement (e.g., binocular disparity in frontally placed eyes). In addition, recent research uncovered unique depth perception cue, retinal defocus, the presence of which in other species remains to be explored (Nagata et al.

2012). Still, it is clear that despite dramatic differences in eye anatomy, number of eyes, location of eyes, and mechanics of neural processing of visual information, many principles of depth perception remain remarkably similar across different taxa. Further research in this area will be essential to our understanding of the basic principles of constructing a successful visual system and to our appreciation of how the properties of a visual system change as a result of its adaptation to a specific environment.

Definition

Devaluing a woman's mate value relative to one's own mate value by criticizing her physical appearance.

Introduction

When people compete against same-sex peers for romantic partners, they typically compete to embody traits that the opposite sex finds attractive (Buss 1988). Consequently, the areas in which women compete with one another are dictated by men's preferences. One trait that men find highly desirable in a potential partner is physical attractiveness (Buss 1988). Sometimes, women's strategy is to enhance their own physical appearance to compete for partners. However, another strategy that women use to compete for romantic partners is to derogate other women's attractiveness. In other words, women attempt to devalue other women's physical appearance relative to their own physical appearance (Buss and Dedden 1990).

What Is Derogation of Attractiveness?

Derogation of attractiveness takes many forms, most of which can be described as indirect aggression (Vaillancourt 2013). Some examples of these behaviors are laughing at or criticizing a woman's appearance, gossiping about a woman's appearance to men or other women, ostracizing or refusing to befriend a woman, or using derisive body language toward another woman (Buss and Dedden 1990; Leenaars et al. 2008). Sometimes, the derogation is subtle and can happen at very low levels of perceptual processing. When chronically jealous women were asked to imagine their partner engaging in infidelity, they exhibited more implicit negative biases toward attractive women than unattractive women (Maner et al. 2009). Specifically, women were quicker to respond when the task required categorizing attractive women with “negative” and women were slower to respond when the task required categorizing attractive women with “positive.” The ease in which women associated attractive women with “negative” and the difficulty they had associating attractive women with “positive” provided evidence of a negative implicit bias toward attractive women.

To Whom Does It Happen?

Many of the characteristics associated with women's attractiveness are also associated with women's fertility (Singh 1993). Targets of derogation tend to be women who are in a fertile stage of their life (i.e., postpuberty, but premenopause). In a sample of high school students, girls who rated themselves higher in attractiveness were more likely to be the targets of indirect aggression than girls who rated themselves lower in attractiveness (Leenaars et al. 2008). The effect of the girls' attractiveness on indirect aggression decreased as the girls' age decreased. This suggests that girls who were less likely to be sexually active (i.e., younger girls) may not have been viewed as rivals and consequently were not targets of sexual jealousy.

Ovulatory effects on women's derogation of attractiveness provide further support that this phenomenon is particularly relevant to women who are at peak fertility. When women are in the fertile phase of their ovulatory cycle, other women may pose substantial threats if they block mating opportunities. A lost mating opportunity when a woman is ovulating is far more detrimental to reproductive success than a lost mating opportunity when a woman is not ovulating. Women's derogation of female rivals is more pronounced when the perpetrator is in the fertile phase of her cycle. For example, women who are in the fertile phase of their ovulatory cycle rate pictures of other women's faces (but not men's faces) lower in attractiveness than women who are not in the fertile phase of their cycle (Fisher 2004).

Effects Outside of Mating Contexts

Derogation of attractiveness is likely motivated by mating motives, but a mating context is not necessary to activate this phenomenon. Not only are women less likely to accept an apology from an attractive woman than they are to accept an apology offered by an unattractive woman, but apologies given by attractive women are evaluated as lower in quality than those given by unattractive women (Phillips and Hranek 2012). Women are also less inclined to hire an attractive woman than

an unattractive woman (Agthe et al. 2011). Finally, women are more likely to attribute attractive women's successes to luck, but they attribute unattractive women's successes to ability (Forsterling et al. 2007). Notably, attributional biases do not occur when female targets are pre-pubescent and thus unlikely evaluated as sexual rivals.

Conclusion

One strategy women use to compete for romantic partners is derogation of other women's attractiveness. Derogation of attractiveness occurs when women attempt to devalue another woman's appearance relative to their own appearance. If women successfully derogate a rival's appearance, they enhance their desirability to potential partners and consequently enhance their reproductive value. Derogation most often takes the form of gossip and dirty looks, but it can also affect a woman's inclination to forgive another woman or approve a woman's job application.

Derogation of Attractiveness Among Women (Intrasexual Rivalry)

Karis Alston, Madalyn Taylor and
Jaime M. Cloud
Western Oregon University, Monmouth,
OR, USA

Definition

The disparagement of a rival's degree of physical attractiveness and the circumstances in which this type of derogation is most common.

Introduction

Intrasexual competition is the rivalry that occurs between members of the same sex in an attempt to secure prospective mates. Both men and women intrasexually compete; however, the manner in which they compete varies drastically. Unlike men, women compete for mates in primarily nonphysical ways. One of the most common forms of

nonphysical female competition is the verbal derogation of other women, particularly in relation to their physical attractiveness. This type of derogation has been shown to negatively influence a man's judgment of a target woman's attractiveness and, consequently, her mate value (Fisher and Cox 2009). This tactic is effective because it provides information relevant to an adaptive problem faced uniquely by men over human evolutionary history: identifying fertile mates. This adaptive problem produced selection pressure on men to find traits predictive of fertility as attractive. These traits include, but are not limited to, a small chin, full lips, large eyes, high cheekbones, a small waist paired with relatively large hips, and large breasts (Gangestad and Scheyd 2005). Consistent with this logic, a vast amount of research shows that men from regions and countries across the globe place great importance on the physical attractiveness of a potential mate (e.g., Buss 1989). Women are therefore expected to derogate the attractiveness of intrasexual competitors to lessen their desirability to potential mates (Fisher and Cox 2009). This behavior has evolved as a prominent strategy for the attraction, acquisition, and safeguarding of high-quality mates (Darwin 1871; as cited in Fisher et al. 2010).

Contexts that Elicit Attractiveness Derogation

The nonphysical, and oftentimes indirect (i.e., not requiring face-to-face confrontation), nature of competitor derogation makes it an especially appealing form of intrasexual competition for women. Campbell (1999) argues that because children are much more reliant upon care from their mothers than their fathers, women evolved to be apprehensive about engaging in situations that threaten the safety of their physical body, and by extension, their offspring. Thus, in many circumstances, women perceive the risk of engaging in physical forms of intrasexual competition as exceeding the expected benefits. It may also be that women avoid physical confrontation to preserve their own attractiveness and maintain their mate value. To date, this alternative explanation has yet to be explored.

Research has shown that while members of both sexes engage in competitor derogation, the focus of their derogation differs dramatically (Buss and Dedden 1990). Whereas men tend to call attention to a rival's lack of resources, women are likely to emphasize a rival's degree of sexual promiscuity (► [Derogation of Promiscuity](#)) and attack the weight, body size and shape, and facial features of other women (Buss and Dedden 1990). This is especially likely to occur at ovulation. Fisher (2004) showed that women were more likely to derogate (i.e., assign lower attractiveness ratings to competitors) during times deemed most critical for the derogators to secure a potential mate, namely, when their estrogen levels, and thus probability of conception, were highest. Additionally, derogation is more likely to occur when the target woman is scantily dressed. Vaillancourt and Sharma (2011) examined interactions between female participants and modestly or sexily dressed female confederates and found that participants were more likely to mock and derogate the sexily dressed confederate's appearance than the modestly dressed confederate's appearance following their interaction. Thus, it appears that when a rival woman is perceived to be highly threatening (e.g., displaying cues of sexual accessibility), women are more likely to derogate her attractiveness.

Women can increase their reproductive success by derogating the attractiveness of competitors (Fisher and Cox 2009); however, what derogating women might not consider is how other women, as well as the potential mates they are attempting to influence, perceive their behavior. Indeed, after listening to a derogator slander another woman, men revised their initial assessment of the derogator to be less benevolent, loyal, and as having less overall appeal as a potential mate (Fisher et al. 2010). These findings are consistent with those of Schmitt and Buss (1996), showing that female derogation strategies were relatively ineffective when compared to female self-promotion strategies. It is therefore reasonable to suggest that in contexts in which potential mates may be firsthand observers of the derogation, self-promotion may be a more effective strategy for female competitors. Nevertheless, derogation can be an influential and advantageous form of intrasexual competition.

A profitable avenue of future research would be to investigate the nature of competitor derogation in different contexts. One key factor might be the sex composition of the audience. Women are expected to be more discreet when derogating other women in the presence of potential mates, given findings that suggest that men find such behavior unattractive (Fisher et al. 2010). Other contexts to explore are those in which the rival woman is clearly and objectively attractive as opposed to ambiguously and subjectively attractive. Presumably, derogation specifically about a woman's attractiveness would be less effective in the case of the former, given that there is undeniable evidence to refute the derogator's claims. Relatedly, future researchers may wish to observe whether the nature and intensity of derogation is influenced by the attractiveness of the potential mate.

Conclusion

Much remains to be discovered about the conditions that trigger intrasexual competition among women, and, in the case of attractiveness derogation, the physical traits that are most likely to be the target of women's derogation. The evolutionary perspective that forms the basis of much of this research will continue to provide novel insights about the motivations, contexts, and consequences of women's attractiveness derogation.

Definition

Condemnation of a woman's casual sexual behavior in an attempt to devalue her mate value relative to one's own mate value.

Introduction

Women should compete with one another to embody traits that men find highly desirable in a potential partner (Buss 1988). Men desire sexually promiscuous behavior from short-term partners, but men do not like for their long-term partners to be sexually promiscuous (Buss and Schmitt 1993). This preference against long-term partners who are sexually promiscuous is a defense against cuckoldry. Before genetic testing was possible, men rarely could be completely certain of a child's paternity. By seeking long-term partners who are not sexually promiscuous, men can increase certainty that they are investing resources into genetically related offspring. Because men's preference for promiscuous women varies depending on the type of relationship they pursue, derogation of promiscuity may not always decrease men's attraction to derogated women. Nonetheless, evidence suggests that women consistently derogate other women's promiscuity.

This effect may be best explained by evidence that women are responsible for the suppression of female promiscuity (Baumeister and Twenge 2002). Women may use sex as a resource to negotiate with men. If women make sex too readily available, the value of sex diminishes. Consequently, women may wish to stifle other women's sexuality if they offer it too easily.

When a woman derogates another woman's sexual behavior, she may achieve two goals. First, derogation may decrease a woman's desirability to men as a long-term partner if the derogation prompts men to question the woman's fidelity. Second, derogation may help maintain the value of sex if the threat of being derogated against prevents women from freely offering sex to men. It is also possible that men could lose interest in some women as short-term partners if they feel that sex is off the table. Although the reasons for women to derogate promiscuity differ depending on the theory, both theories suggest that women should be motivated to derogate other women's sexual behavior.

What Is Derogation of Promiscuity?

Derogation of promiscuity occurs when someone condemns another woman's casual sexual behavior in an attempt to devalue the woman's mate value relative to one's own mate value. Women may gossip to other women or men about a woman's sexual history, they may refer to a woman with derogatory names such as "slut" or "whore," they may call into question another woman's fidelity, they may give another woman a dirty look or other negative body gestures, or they may physically threaten another woman if she seems sexually available (Leenaars et al. 2008; Vaillancourt 2013). In a sample of school girls and prison inmates, women reported that derogation of promiscuity was one of the most common reasons why they engaged in physical violence with another woman (Campbell 1986). The perpetrators were the women defending their reputations from the derogatory remarks.

Women are also less inclined to befriend women whom they deem to be too sexually available (Bleske and Shackelford 2001). Ostracism of promiscuous women may be driven by a fear of "guilt by association," or it may be driven by a fear that a promiscuous woman could lure away one's partner. Indeed, women are particularly upset upon imagining another woman acting sexually available to attract their partner (Bleske and Shackelford 2001).

To Whom Does It Happen?

A woman's sexual history is associated with derogatory actions toward her. Upon reading the description of a promiscuous woman, women report less desire to befriend someone like the woman described (Bleske and Shackelford 2001). In a sample of high school girls, as the number of recent (i.e., within the last month) sexual partners increased, their odds of being derogated against significantly increased (Leenaars et al. 2008). Derogation was measured by self-reports of how often they had received hurtful notes, had been excluded from activities, had

rumors spread about them, or had been physically threatened by another student. Notably, these effects were not present for the younger high school students. This finding supports the idea that derogation is an intrasexual competition strategy. Sexual activity is less common in younger adolescents compared to older adolescents, so the younger students were probably in less direct competition with each other relative to the older adolescents.

People rarely have direct knowledge of other people's sexual behavior, so derogation of promiscuity is not always triggered by *actual* promiscuous behavior. Quite often, derogation is triggered by cues that someone *may* be promiscuous. For example, women wearing red are evaluated as more sexually receptive than women wearing white or green (Pazda et al. 2014). Women are more likely to call into question a woman's fidelity when she is wearing red than when she is wearing white.

Women also derogate women who are wearing sexy or revealing clothing, presumably because women may suspect that choice of dress advertises sexual availability. Compared to women who interact with a conservatively dressed woman, those who interact with a sexily dressed woman display more negative facial expressions, more dismissive behavior, a more sarcastic tone of voice, make more negative comments about the woman, and are more likely to laugh about the woman behind her back (Vaillancourt and Sharma 2011). Even when a sexily dressed woman is overweight, women are less inclined to introduce the sexily dressed, overweight woman to their boyfriend than a thin, conservatively dressed woman. Further, women are less likely to befriend women who are dressed sexily than women who are dressed conservatively.

Conclusion

Derogation of promiscuity may be driven by two motives: to decrease other women's mate value and to maintain the value of sex as a resource. Strategies used to derogate promiscuity range from gossip and dirty looks to ostracism and

threats of physical violence. A woman's recent sexual history may make her the target of derogation, but simply wearing red or provocative clothing may also prompt derogation in the absence of actual promiscuous behavior.

Derogation of Promiscuity Among Women

Madalyn Taylor, Karis Alston and
Jaime M. Cloud

Definition

Disparaging a rival's sexual promiscuity as a form of intrasexual competition among women.

Introduction

Intrasexual competition is the rivalry between members of the same sex in an attempt to secure a potential mate. One manner in which women compete for mates is the verbal derogation of rival women. This behavior can take many forms (e.g., attractiveness derogation; ► [Derogation of Attractiveness](#)), one of the most common being the derogation of a competitor's sexual promiscuity. The effectiveness of this tactic is rooted in an adaptive problem faced uniquely by men: paternity uncertainty. Women's concealed ovulation paired with internal fertilization presents an opportunity for women to cuckold their partners, resulting in a nonzero chance that offspring are fathered, not by a woman's primary partner but by an intrasexual rival (Symons 1979). As a solution to this adaptive problem, men seek qualities in a potential mate that increase their probability of paternity, such as premarital chastity and post-marital sexual fidelity (Buss 1989; Buss and Schmitt 1993; ► [Preferences in Long- Versus Short-Term Mating](#)). Thus, by calling attention to or misrepresenting a rival's degree of promiscuity, women decrease the desirability of competitors.

The Costs and Benefits of Derogating a Rival's Promiscuity

Women have been shown to disclose information that a target woman is sexually promiscuous in an attempt to influence a potential mate's evaluation of that woman (Baumeister and Twenge 2002; Buss and Dedden 1990). This tactic produces a twofold effect: it casts doubt about the future fidelity of a rival woman while simultaneously suggesting that the derogator would remain faithful in a future relationship. Relatedly, disparaging rivals has been argued to increase the derogator's self-esteem, potentially increasing the probability that she initiates a romantic relationship or advertises herself as having high mate value (Fisher and Cox 2009).

While effective, women might not derogate another woman's promiscuity because of the potential for this behavior to decrease the derogator's overall desirability in addition to the target woman's desirability (Fisher et al. 2010). Furthermore, derogators run the risk of directing the attention of potential mates to rival women, whom they might not have otherwise noticed or considered romantically. The effectiveness of derogating a competitor's promiscuity is therefore expected to be context specific and deployed only in situations in which the probabilities of the intended benefits are high and the unintended consequences are low. Consistent with this logic, Schmitt and Buss (1996) found that denigrating a rival's sexual history was more effective in the context of a long-term relationship than a short-term relationship, as men find cues of sexual accessibility more desirable in the latter than the former (Men's Preferences in Long- Versus Short-Term Mating). In sum, women seem to be aware of what men desire in both long-term and short-term relationship contexts and may shift their derogation tactics accordingly in order to effectively decrease the perceived mate value of rival women.

An interesting direction for future research would be to compare the relative effectiveness

of various forms of derogation. Some traits, such as a competitor's physical attractiveness (► [Derogation of Attractiveness](#)), may be less effective targets of derogation because they are more easily observable – and therefore, refutable – than other traits, such as a woman's purported degree of promiscuity. In addition, researchers should explore how a woman's relationship status affects the nature of her derogation tactics. Women in committed relationships, who seek to prevent their mates from switching partners, risk enticing their mates into having a short-term affair by sharing information that a rival woman is sexually accessible. Clearly, much remains to be discovered about the costs and benefits of competitor derogation and the contexts in which one form of derogation takes precedence over others.

Conclusion

In the competition for mates, women have been shown to derogate an intrasexual rival's degree of promiscuity; however, this tactic decreases the desirability of rival women in some circumstances more so than others (e.g., long- vs. short-term relationships). Future research that applies an evolutionary perspective will bring the context-dependent motivational structure that underlies women's derogation into focus.

Competition; Lack of respect

Definition

If an individual derogates another, it means to perceive or treat them as being of low worth and with no respect. If an individual behaved like this with a rival, it would be a person who seems equal or comparable to them and a potential competitor at any given task, for example, if they were applying for the same job.

Introduction

Following from the previous chapter, this entry focuses on how individuals may use manipulative communication with others via derogating rivals in order to protect or enhance their self-esteem. It will also demonstrate how the specific personality construct, narcissism, may accentuate this from an evolutionary perspective.

Competition and Derogation

The process of attracting a mate is competitive, sometimes because numerous individuals can be simultaneously attracted to the same person (Alexander 1979; Buss 1988). One way to compete with rivals in order to create better evaluations from potential mates is to derogate the traits and attributes of other competitors. Buss and Dedden (1990) investigated the forms of derogation tactics both males and females use. They found that tactics such as spreading rumors about the competitor, calling the competitor boring, and derogating their intelligence was equally common in both males and females. In addition, males were more likely to use tactics that derogated the competitor's achievements, financial resources, and strengths, whereas females were more likely to use tactics the derogated their competitors' appearance and sexual fidelity.

This behavior is particularly likely in those individuals with high levels of narcissistic traits due to their manipulative and self-enhancing behavior they present to preserve and protect their self-esteem (Goncalves and Campbell 2014). Bushman and Baumeister (1998) conducted a study investigating narcissism and competition by measuring participants' responses when given the opportunity to aggress against someone who had insulted them, praised them, or against an innocent third person. They found that the combination of narcissism and insult produced very high levels of aggression toward the source of the insult.

In addition, Goncalves and Campbell (2014) investigated the relationship between the dark triad (psychopathy, Machiavellianism, and narcissism) and derogating mating rivals. They found

that psychopathy was linked with endorsing tactics that damaged their rival's reputation. Machiavellianism was associated with a rude derogation style, and narcissism was associated with a derogation style where individuals tried to outperform their competitor in different situations such as sports, strength, and dominance. These findings for narcissists are not surprising due to their domineering need to succeed and be seen in a position of superiority compared to others.

Conclusion

An individual can derogate another when they feel in competition, particularly when it concerns attracting a mate. Research has found that this behavior is particularly likely in those individuals with high levels of narcissistic traits. This competitive behavior seen in narcissists could be viewed as manifestations of a short-term mating strategy as it could elevate them to a top position in a social hierarchy (Holtzman and Strube 2011). The derogation of rivals is another example of manipulative communication with others in order to protect or enhance self-esteem.

Descent Illusion, The

Russell Jackson

University of Idaho, Moscow, ID, USA

Definition

The Descent Illusion is the tendency to overestimate a vertical height more while standing on top of it than while standing at its bottom. Predicted from *Evolved Navigation Theory* to have evolved in response to greater falling risks on descent than ascent, it is ostensibly the largest known distance illusion.

Introduction

I predicted the Descent Illusion from my Evolved Navigation Theory (Jackson 2005; *Evolved Navigation Theory*, this volume). Evolved Navigation Theory specifies how natural selection can result from navigational consequences.

The Descent Illusion

A major source of selection resulting from navigational consequences over evolutionary

time is the act of falling, which continues to kill and injure modern humans more broadly than any other accidental source (Verma et al. 2016). One predictor of the likelihood and severity of falling is the direction of travel, where descent results in falls more often and more severe than ascent (see Jackson and Cormack 2007).

Many of the reasons that descent is riskiest derive from human biometry. Descent, compared to ascent, places our eyes farther from the navigated surface. Our bodies lean away from the primary traction source and the direction of travel. Forward momentum coincides with gravity, making acceleration easily overwhelming. Descent limits the efficacy of our hands to interact with the surface, opposite to the natural posture during steep ascent. Additionally, the movements of descent are comprised of short, guided falls consisting of negative muscle contractions that are more difficult to control than the movements of ascent. Many of these aspects of descent occur for other, nonhuman, animals.

Paired with the identification that falls are more common and severe on descent than ascent, Evolved Navigation Theory also identifies that distance perception is one of the cognitive mechanisms targeted by such selection over evolutionary time. For starters, distance perception generally features high variation upon which selection can act. Further, there is a strong Preference for the Nearest (PfN) of otherwise equal navigational goals (Jackson 2013). Selection on distance perception for specific surfaces would thus make overestimation adaptive for biasing navigational choices against navigation of those surfaces. Evolved Navigation Theory predicted that the greater mortality resulting from descent than ascent should have produced an overestimation of vertical surfaces more from above than below. This is exactly what we find.

The Descent Illusion consists of overestimating the vertical extent of an environmental surface more while standing at its top than bottom (Jackson 2005; Jackson and Cormack 2007; Jackson and Gómez de García 2016). This includes overestimating the vertical, in

comparison to an equal horizontal, from both the top and the bottom of the vertical surface (each of which separately constitutes an Environmental Vertical Illusion [Jackson and Cormack 2008]). Standing at the top or bottom of a vertical surface does not induce general distance overestimation: Observers estimate horizontal surfaces accurately or with slight underestimates, on average (Jackson and Willey 2011). The formula for the Descent Illusion is $\frac{(et - eb)}{eb}$, in which *et* is the estimate from the top and *eb* is the estimate from the bottom (Jackson and Cormack 2007).

The average magnitude of most distance illusions is roughly 10–15%. The average magnitude of the Descent Illusion is roughly 25–30%. Further, Descent Illusion observers' overestimates of a vertical surface while standing on top of it, compared to their estimates of an equal horizontal surface, exceed 80% on tall surfaces. This is ostensibly the largest known distance illusion.

This phenomenon is ubiquitous in everyday vision and yet humans are largely unaware of experiencing it (Jackson et al. 2013). It has been replicated across different real-world (Jackson 2005, 2009) and virtual environments (Jackson 2017), as well as across cultures and groups that include indigenous people selected explicitly for their disparities with previous samples (Jackson and Gómez de García 2016). This illusion redefines acrophobia as a normal fear of overestimated distances, rather than an abnormal fear of standard perception (Jackson 2009).

Conclusion

Competing theories failed to predict the Descent Illusion (Jackson and Cormack 2007), which is but one of many illusions and other cognitive mechanisms predicted by Evolved Navigation Theory (*Evolved Navigation Theory*, this volume). Although visual illusions are one of the earliest and most robust topics in psychological science (see Jackson and Cormack 2007; *Visual Illusions*, this volume), it was not until we utilized evolutionary psychological science that we were able to predict the largest among them.

Distinctive qualities of human language

Introduction

Some general conclusions apply to all communication among living organisms. Communication, even in nonhuman animals, has unexpected complexity; it is a form of cooperative behavior; it includes individual recognition and categorization; and it requires the development of associations and thus memory. Furthermore, noise in communication is inevitable. Critical terms, such as information, signal, and noise, require operational definitions (for more on these topics, see ► [“Evolution of Communication”](#)).

These conclusions change basic assumptions about the relationship between nonhuman and human communication. Communication by nonhumans is more complex than expected and

communication by humans, as presented in the following sections, perhaps less so. There is clearly a large difference in brain size, cognition, and communication between humans and most other animals. Nevertheless, overstating a difference hinders comprehension just as much as understating it.

For centuries people have sought objective criteria to separate humans from other animals, and language has often taken first place among these criteria. Once Darwin and the early ethologists made it clear that nonhuman animals also have elaborate communication, the focus has narrowed to the properties of language that distinguish humans. Each such proposal has spurred students of animal behavior to probe deeper for parallels among nonhuman animals. Some organization in this process came when Charles Hockett (1960) presented a set of 16 “design features,” or distinctive properties, of human languages. Some of these features, such as a vocal-auditory channel (with its concomitants, broadcast transmission, directional reception, and rapid fading), interchangeability, and specialization are easily identified in diverse nonhuman animals. The remaining design features have more problematic parallels in nonhuman animals. Some of the issues they raise invite applications of the general conclusions listed above. The following discussion focuses on illustrative examples, rather than a general review, of these parallels.

Cultural Transmission

Culture is widespread in species with persistent associations of parents and offspring, but it is also prevalent in many species with less complex social behavior. Culture develops when patterns of behavior are acquired by young individuals as a result of experience with older ones. Prevalent examples in nonhuman animals include migration routes, territory boundaries, mating preferences, food selection, and predator recognition. Cultural transmission in humans as well as in other animals includes relatively unconstrained learning. Possibilities for learning have broad scope within wide predispositions. Nevertheless, the

study of nonhuman animals has revealed that even impressively open forms of learning have constraints that guide learning in adaptive ways. For rapid acquisition of complex traits within adaptive boundaries, learning within constraints is perhaps the optimal method. Such constraints (or predispositions) can for instance ensure that learning occurs within species, a particularly clear example of which is song learning by oscine birds. In this case, predispositions must affect responsiveness as well as production. Nevertheless, identifying predispositions for acquisition of human language remains contentious.

Animals other than humans rarely, if ever, appear to engage in teaching, in which an experienced individual directs the attention of an inexperienced audience to a task. Cultural transmission instead appears to result predominantly from observational learning by young individuals in the presence of adults performing routine activities (Matsuzawa 1999). A recent experiment with great tits reveals that observational learning can produce persistent cultural traditions in the feeding behavior of birds, even when the tradition is maladaptive (Aplin et al. 2015). In contrast, schools or apprenticeships are perhaps universal in human cultures. Nevertheless, it is possible that much, perhaps most, of human culture is instead transmitted by observational learning.

Cultural traditions in the songs of passerine songbirds, parrots, and hummingbirds illustrate one of the usual consequences of culture, the differentiation of dialects or traditions among nearby populations. All species of songbirds appear to learn at least some features of their songs. With few exceptions these species develop prominent geographical variation in their songs, whereas songs of other species vary only slightly, in line with variation in morphology. When the individuals of a species sing a single song pattern, all those in a limited geographical area often learn the same distinctive pattern. When individuals have repertoires of songs, dialects often intergrade as the frequencies of different acoustic patterns change progressively but incoherently with location (Marler and Slabbekoorn 2004; Kroodsmas 2005; Podos and Warren 2007). When individuals

sing only one pattern each, the formation of dialects is perhaps simplified. Nevertheless, distinct dialects in the vocalizations of some parrots and cetaceans include coherent repertoires of patterns.

Geographic differentiation of culture depends on the relationship between two periods in an individual's life: when a young individual learns the relevant behavior and when and where it moves before it eventually settles. The formation of distinct dialects requires either that young birds usually settle within the area of their natal dialects or that learning after settling predominates over earlier learning. In the case of coastal populations of white-crowned sparrows in California, individuals usually sing only one pattern, and dialects occupy nearly distinct areas with irregular shapes 2-20 km across. It remains uncertain whether the songs a young sparrow eventually masters are influenced by experience predominantly before or after dispersal. Conversely, it is also unclear whether or not a young sparrow's decision about where to settle is influenced by early experience.

Furthermore, it is also unclear whether or not dialects in birdsong are evolutionary adaptations (Podos and Warren 2007). Adaptation is a result of natural selection, the spread of alleles associated with advantages for individuals' survival or reproduction. In one possible scenario, dialects might result from adaptations for efficient signal detection in different environments. Alternatively, dialects might promote local adaptations for survival or reproduction in general, by restricting gene flow to populations in distinctive environments. Another possibility is that dialects might arise as collateral effects of the evolution of learning, if, for instance, complex learning was in itself important for mate choice. Or dialects might arise as side effects (pleiotropy) of local adaptations for noncommunicative purposes in structures also used for communication, for instance, if the structure of birds' bills adapted to the characteristics of their food but also constrained the kinds of sounds they could produce. In the latter two situations, the formation of dialects would in itself have no influence on individuals' survival or reproduction. In any case, dialects might promote the genetic divergence of populations and ultimately contribute to the origin of separate species.

All of these issues about dialects apply to human cultures as well. The maintenance of human languages and dialects indicates that individuals learn from older individuals within their natal area and then predominantly settle nearby. The increasing frequency of exceptions in recent centuries is presumably changing the geography of human languages. Each individual's choices of mates and places to settle are no doubt to some extent influenced by their natal language. Important but infrequent exceptions are the abduction of individuals and the translocation of populations as a regular consequence of warfare between culturally distinct groups. No doubt the boundaries between languages are influenced by interactions across these boundaries, but differentiation of languages in turn influences the nature of these interactions.

In contrast to birdsong, human language is distinguished by two levels of geographic differentiation. At one level, there are mutually incomprehensible "languages," which in their geographic pattern resemble the distinct dialects of songbirds. At another level, human "dialects" within a language intergrade more or less progressively, like geographic variation in the frequencies of song patterns of birds that have repertoires. Perhaps more study of songbirds would also reveal multiple levels of geographic differentiation.

A related design feature, learnability, refers to the human ability to learn more than one language. In songbirds with vocal dialects, individuals usually respond to dialects other than their own, although sometimes less so to distant dialects (Searcy et al. 1997). Furthermore, just as children are adept at learning any human language, songbirds acquire any dialect of their species-specific song with apparently equal facility. Bilingual individuals also occur among songbirds. Although careful comparisons are lacking, bilingual proficiency is perhaps as frequent as it is in human populations. Bilingual competence is hard to confirm when individuals sing multiple patterns that vary incoherently with location. When dialects are distinct, on the other hand, persistent study often reveals the presence of bilingual individuals. Most white-crowned

sparrows that settle near a dialect boundary sing only the pattern appropriate for their dialect, but some individuals near a boundary are indeed bilingual, with two song patterns, one matching each nearby dialect (Baptista 1977). To clarify these parallels between human and nonhuman cultures, the spatial and temporal properties of the transmission of signals and responses, in relation to the dispersal of individuals, need more attention, both in humans and nonhumans.

Despite these open questions about the process, geographical differentiation is one of the salient features of culture, both human and non-human. This differentiation requires errors in cultural transmission and thus reveals a crucial effect of noise in communication. Even if cultural traits have adapted to particular social or physical environments and even if migration of individuals introduces novelties in new areas, nevertheless errors must initiate the process of cultural change somewhere. Errors in cultural transmission are analogous to genetic mutations, insofar as both are transmitted to subsequent cohorts, although the rates of innovation and mutation can differ. Migration is similar in the two also, except that migrating individuals can abandon cultural traits but do not change genes (although the expression of genes might change). Cultural and natural selection, on the other hand, lack close analogy. The plasticity of individuals' traits, the rates of transmission, and the recipients all can differ markedly. Nevertheless, in the case of human languages, the stability and restricted acquisition of language might approach that of genetically canalized phenotypes. Close relatives usually play a predominant role in transmitting language. Language proficiency by humans requires years to develop and then, after the lapse of sensitive periods for acquiring some features of language, changes with great difficulty.

The transmission and innovation of culture depend on communication. Unless completely arbitrary, without advantages or disadvantages for signalers or receivers, this communication evolves by the same process of mutual optimization that applies to the evolution of all communication (see ► [“Evolution of Communication”](#)).

The advantages for signalers depend on the behavior of receivers, and the advantages for receivers depend on the behavior of signalers. Errors, from multiple sources, are inevitable. Even perception evolves by optimization with errors. The crucial role of errors, in other words noise, in all communication and perception means that culture, in humans or other animals, cannot be understood without studying errors. In studying the evolution of birdsong, the variation in learning is as important as the norm. The same is true of all human culture, including language. Yet studies of culture have usually focused on the norms, to the exclusion of the errors. Understanding communication requires attention to exceptions as well as norms.

Semanticity, Displacement, Arbitrariness, and Discreteness

This set of Hockett's design features refers in one way or another to how signals are related to situations. Many animals use discrete signals. Discrete signals are likely to improve discrimination by receivers and thus could have advantages in noisy situations such as long-range communication. In line with this expectation, discrete articulation might be more pronounced in long-range speeches by humans than in close-range conversation. This variation in discreteness would exemplify the scaling of exaggeration in signals with the level of noise, as predicted for the evolution of all communication in noise (see ► [“Evolution of Communication”](#)). More study of variation in signals with contexts could clarify this issue.

Arbitrariness refers to separation of a signal from direct resemblance to or evocation by its referent. Warning calls, for instance, do not resemble the sounds of predators. On the other hand, the pitch or tonality of sounds in some cases directly reflects an individual signaler's overall physiological state, such as its tendency to flee, fight, or freeze (Morton 1977; Reby et al. 2005). Arbitrariness is intended to denote a signal's association with a more cognitive internal state, a specific neurophysiological state rather than a general

physiological or emotive one. These alternatives, of course, are the ends of a spectrum of possibilities. Each case lies somewhere between a scream of fear and an abstract notion. Human speech conveys information about a speaker's general states, or emotions, in addition to and concurrently with specific states or abstractions. Any signal has some degree of arbitrariness and some degree of abstraction. No doubt human language includes more cognitive complexity than other animals' signals. An unanswered question though is whether or not it might also include more emotive complexity. This continuum between emotive and cognitive applies to the next two design features also.

Note in passing that arbitrary signals in discussions of sexual selection are defined differently. They have zero utility for receivers and, as argued elsewhere, seem highly unlikely in noisy communication (see ► [“Sexual Selection”](#) and ► [“Evolution of Communication”](#)).

Semanticity and displacement are related to information in signals about the external environment. Some of the best examples of semanticity in nonhumans are warning calls and food calls. Semanticity applies to signals associated with external referents in contrast with those expressing the signaler's internal states. This distinction is just as untenable here as in the previous paragraph. Recall from previous sections that all of an individual's actions are influenced by both its internal and its external state, by both its current constitution and its impinging sensations. Rather than a distinction between signals that are emotive versus cognitive, there is instead a continuum from more emotive to more cognitive. The question is where particular instances of calls lie on this continuum from emotive to cognitive.

Playbacks show that individuals respond appropriately to alarm or food calls even in the absence of an actual predator or food. Furthermore, some birds and mammals have distinct calls for two or more predators that pose different threats, and playbacks of these calls evoke the appropriate responses. The associations with different predators are in some cases learned. Young vervet monkeys reliably

produce the correct calls only after prolonged practice (Cheney and Seyfarth 1990). Many birds in contrast easily learn experimental associations of predator calls with various improbable objects. It is thus clear that some nonhuman animals can learn to produce, and to respond to, signals associated with specific external situations, and in some cases these associations are learned easily.

On the other hand, in normal circumstances these calls are produced and evoke responses, only in the presence of actual predators. Displacement, in contrast, refers to separation of a signal and its referent in space and time. This separation requires memory. With displacement, the cognitive rather than emotive associations of signals, and thus their semanticity, often seem clearer. Furthermore, relatively more cognition is suggested by two forms of noise in communication: unreliable and deceptive signals. Adult vervet monkeys, for instance, learn to ignore the unreliable calls of young individuals (or unreliable adults) (Cheney and Seyfarth 1990). Furthermore, some monkeys and birds produce predator warnings deceptively in the absence of a predator, as discussed further below. Errors in communication, the apparent exceptions, provide intimations of cognition.

Displacement is also attributed to the waggle dances of honeybees. These dances in a hive or a swarm indicate the location of food or potential nesting sites by means of two transpositions. The direction to the goal with respect to the sun becomes the direction of a waggle dance on a vertical surface with respect to gravity, and the total energy expended in flight to the goal becomes the instantaneous expenditure of energy in the dance. The levels of arbitrariness and semanticity are both low. The mapping of direction and distance onto the signaler's overall behavior and the limited memory remove this case from typical human cognition. Arbitrariness, semanticity, and displacement again contribute to a continuum between emotive and cognitive behavior. All are widespread in communication. All are disrupted by noise. Yet their use in noise sometimes reveals a degree of cognition.

Prevarication

Hockett's final design features are at the top of his proposals for human specializations. Nevertheless, there are reports of prevarication, or deceptive use of signals, in many birds and mammals. Predator calls, in particular, can serve to distract higher-ranking opponents so that low-ranking ones have a chance to obtain food or matings. Analysis of communication in noise shows that opportunities for such deception are expected in all forms of communication (see ► [“Evolution of Communication”](#)).

Nevertheless, linguists often balk at attributing true prevarication to nonhuman animals, in the absence of evidence for the signalers' intention. Intention becomes one of the definientia of deception. Does the signaler expect or plan to deceive the receiver? How does a person expect or plan to take advantage of another person? Presumably the actor anticipates a personal advantage based on anticipation that the recipient is vulnerable. In the case of deceptive communication, the signaler thus anticipates that a particular receiver is likely to respond in a way that yields an advantage to the actor despite a disadvantage to the receiver. This anticipation is tantamount to mind-reading or having a “theory of mind.” There is a circularity here: an actor has intentions provided it can read another's mind, and primary evidence that an actor can read a mind is provided by thoughts such as intentions.

Such circularity in discussions of mental phenomenon excludes not only nonhuman animals from a thinking person's mentality but also all other humans. An operational definition of deception, which avoids such circularity, is a system of signals directed specifically (nonrandomly) at receivers from which a response, on average, has advantages to the signaler but disadvantages for the receiver. Such signals require some preliminary strategy. Because responding to signals should evolve to increase a receiver's advantage in reproduction or survival, deceptive signals, which have the opposite effect, must in general occur infrequently. Consequently, deception often reveals evidence of a cognitive ability by signalers to adjust the frequency of attempted deceptions by

itself and others. For instance, a deceptive signaler might anticipate a particular receiver's probable response; in effect it might read its mind, from the temporal context of signaling.

Reports of deception by nonhuman animals indicate that this behavior is, as expected, usually dependent on the circumstances of the audience. Signals that call attention to the presence or location of food often depend on whether the audience is likely to be a competitor or a partner. Recognition (categorization) of individuals, not just broad classes of individuals, is often critical. Anticipation of the state of the audience is of course widespread in nonhuman signaling, but this attribution applied to specific individuals matches the kind of behavior associated with intentions, as just defined. It presumably occurs in many sorts of social interactions, from anticipatory cooperation to strategic aggression (Cheney and Seyfarth 1990, 2007; Seyfarth and Cheney 2014). It applies to roosters advertising food to attract hens (Gyger and Marler 1988), to subordinate males courting females without drawing the attention of dominant males (Smith et al. 2011), and to territorial warblers challenging specifically those neighbors that have trespassed (Godard 1993). The complexity of an organism's “theory of mind” depends to a large degree on the complexity of its categorization of the individuals it interacts with. Furthermore, intentions in the form of signals adjusted to contexts, whether human or nonhuman, are subject to errors.

Duality of Patterning and Openness

These final, and most problematic, design features are closely related. Openness in human language, an ability to rearrange units of sound to produce new phrases, depends on duality, the organization of speech into at least two hierarchical layers. Elements of a lower layer, which in themselves have little or no meaning, are arranged to produce units of higher layers, which do have meaning. As previously suggested, the operational definition of the “meaning” of a signal, in a particular context, is the receiver's usual response, overt or covert, immediate or remembered. Language is often described with three layers, phonemes,

morphemes, and phrases (sometimes with syllables of phonemes interposed), of which only phrases convey meaning. Duality of patterning requires two layers arranged so that recombined discrete components of one layer are nested within components of the other.

Many nonhuman animals have substantial repertoires of discrete signals (see ► [“Evolution of Communication”](#)). In those species that produce sequences of signals, some recombine signals into larger performances. Some songbirds use the same components in different sequential patterns of song, but some use different components in each sequential pattern. There is sparse evidence that the different sequential patterns in these repertoires convey different information, for instance, by association with different contexts or internal states, or evoke different kinds of response (Wiley et al. 1994). An absence of evidence is particularly inconclusive here, because finding significant associations with complex patterns of recombining elements becomes statistically challenging. Anthropologists have a big advantage in deciphering a previously unknown human language, as a result of their preconceptions about what humans are likely to talk about. Humans, in other words, have an anthropocentric theory of mind, one that provides much less help in deciphering communication of other species. Humans perhaps should not underestimate other animals.

Despite these possibilities for other species, human language no doubt has remarkable capability to recombine components of signals to convey a vast complexity of information. Nevertheless, components of language are not nearly so distinct in actual speech, in all its various contexts, as they are often presumed to be. Contextual and individual variation in phonemes and morphemes is well known. Furthermore, everyday conversation might depend heavily on phrases as units, learned for production and response as units, rather than as recombined components. All languages are beset with idioms and pat phrases, particularly for routine communication, phrases learned as units rather than by rules. In English, few people know the expressions “thin as a rail” or “what’s up,” for instance, as anything other

than “thin-as-a-rail” or “whats-up,” single units of expression, not recombining units. Another example is the instability of prepositions (and grammatical cases). Across and within languages, association of prepositions with contexts often defy consistent definition and instead become erratic or idiosyncratic. Most of these associations are presumably learned and deployed as units without parsing. Proficiency thus might often depend on mastering associations of these unitary phrases. Even when some parsing of recombined components is necessary, the associations of phrases can depend on common underlying metaphors (Lakoff and Johnson 1980). Indeed, morphemes raise the same questions. Many words are sequences of two or more syllables, which in combination evoke unitary associations. Etymological stems for syllables are rarely parsed. Even then underlying metaphoric associations dominate. Thorough study of the variability of human speech at all levels might reveal that duality of patterning requires a dose of grammatical fantasy.

The deployment of writing in itself changes communication. Writing allows much greater permanence than does neural memory alone, and this permanence allows a reader, as a receiver of signals, to examine and even to review the structures of phrases more carefully than is possible in conversation. With time available, humans can indulge their drive to categorize, by abstracting, cataloguing, and eventually prescribing patterns of usage. In reality both human and nonhuman communication are permeated with unexpected variation, as a result of errors in production, transmission, or reception of signals, but also just idiosyncrasies in usage by individuals or small groups of communicating individuals. The irregularities, idioms, idiosyncrasies, and errors are an inescapable part of language.

Openness is an abstraction or exaggeration of reality as well. Although linguists often claim infinite possibilities for language, the components of language are finite, the human brain is finite, and the practical possibilities for combinations are finite. Speaking humans do not produce stereotyped phonemes that recombine to form stereotyped morphemes and then phrases with unlimited possible meanings. The number of possible

associations is no doubt large, but the number of associations humans make in using language might not exceed the number of associations they make in categorizing other humans (Wiley 2013). Errors also limit associations of attributes with other objects.

Furthermore, limited evidence is a temptation for simplification of nonhuman animals' behavior. For instance, songbirds are usually thought to have repertoires of distinct patterns of notes, from one to several hundred such patterns. Careful inspection, however, reveals much variation in details, little or none of which has any current explanation. Perhaps even greater complexity in sequences of sounds occurs in cetaceans. The difficulties of investigating complex signals include the impediment of lacking an appropriate theory of mind on which to base hypotheses. Nevertheless, much variation is no doubt meaningless, just as it presumably is in human speech.

A promising way to investigate variation consists of looking for dependence in recombinations of components. A simple example is provided by displays of the Carib grackle (Wiley 1975). Males perform conspicuous displays to females and other males. Each display involves raising wings, tail, and bill to varying degrees. Elevated wings show some association with displays toward females, elevated bills with those toward males. Because these displays are easily observed, a large number can be scored for each element. Analysis reveals that wing and tail elevation are independent of each other, so in this case this species has the potential to generate infinite gradations of wing and bill elevation, each presumably related to neural and mental states while interacting with females and other males. This example of insipient duality and openness indicates how difficult it can be to decide whether complex variation in signals is relevant, erroneous, or simply adventitious.

Hierarchical Organization

As awareness of the complexities of nonhuman communication has accumulated, attention has focused on hierarchical organization as the key

to the relative openness of language. Although responses to "sign stimuli," simple sensations, occur widely, especially in the initial responses of young organisms or in the quick avoidance of predators, nevertheless, responses to more complex stimulation are also widespread. For instance, many vertebrates, but not humans, have neurons that act as movement detectors, even at low levels of sensory processing. Recognizing patterns is not an unusual capability of many other animals. Although birds and mammals soon after hatching or birth have reflex (highly canalized) responses to simple stimulation associated with predators, they often quickly learn more complex associations. Object constancy, an ability to recognize (form associations with) a set of sensations as a unique object despite varying perspective and occultation, does not differ in principle from other forms of recognition, including recognition of individual conspecifics or recognition of verbal sequences. Recognition of patterns, spatial or temporal configurations of components, is thus a mental capability that occurs widely in animals as well as humans.

Much recognition is potentially hierarchical. Any particular instance of a set of sensations could be recognized as belonging to one or more progressively more inclusive and complexly embedded or overlapping categories. A territorial neighbor can be recognized, for instance, despite singing multiple different song patterns, at different locations and distances, under different environmental conditions. Furthermore, it might be recognized more specifically as one that had recently trespassed or one known from a previous year (Godard 1991, 1993; Wiley et al. 1994; Godard and Wiley 1995). Hierarchical categories are recognized by Aristotelian definition, with consistently defined features. Alternatively, categories might be recognized by family resemblance, with inconsistently shared features. In the first case, all members of a category would share an inclusive set of features, as in a phylogenetic tree. Membership in categories would be unambiguous. In the second, members of a category would each share some but not necessarily the same set of features with every other, as in an actual family. Ambiguity might occur.

Chomsky (2005) recognized the importance of categorization when he proposed that merging is the crucial cognitive operation of language. Merging, in the usual sense of simple combining, is nevertheless too simple for his examples, which require combining elements from two separate categories, subjects and predicates, in order to produce a phrase with meaning. In more physiological terms, Chomsky's merging is not just association of perceptions but association of elements from two categories of perception. Associating perceptions from two categories is cognitively similar to associating individuals with different contexts. It is a matter of common experience that contexts affect recognition of individuals, presumably because objects such as individuals become associated with their contexts. Thus each context merges, in Chomsky's sense, more easily with some individuals than with others, just as each verb merges more easily with some nouns than others. In this way, parsing social interactions might require cognitive abilities that could be coopted for language. Yet it is not clear whether the relevant categories are recognized by definition or by family resemblance. Furthermore, both in language and social interaction, associations might sometimes be recognized as units, without any parsing, in other words, without any analysis and merging of parts, at all.

Consequently it seems unlikely that either language or social interaction is organized entirely hierarchically. Nevertheless, this particular form of organization has received special attention as a possibly fundamental feature of language. Hierarchy connotes two distinct kinds of organization. Human institutions are hierarchical in the sense of a chain of command, with each individual overseeing a set of subordinates. The organization is like a multidimensional pyramid, with lower sets embedded (nested) within higher sets. In contrast, tennis players and perhaps society mavens are ranked unidimensionally, in a ladder. In non-human social organization, dominance hierarchies take the latter form. An example of such a pattern is $(A > B > C > D)$ where A through D are individuals ranked on a single dimension. Embedding in this case consists of pairs of closely ranked individuals inserted between pairs of distantly related

individuals, $(A > (B > C) > D)$. Human language is also linearly ordered in time (speech) or space (writing), with similar nestings of components, where A through D are words (morphemes). Several experiments have suggested that birds can recognize sequences like (AABB) or (ABBA), although it is not clear that they can generalize such a pattern to new exemplars (Van Heijningen et al. 2009). The second sequence superficially matches a pattern of embedded phrases in language. On the other hand, the first, not the second, sequence matches complex dominance hierarchies that result when individuals' rankings are embedded within families' rankings or when dominants create coattails for familiar subordinates. There are indications that baboons and birds can "parse" a dominance hierarchy with embedded clusters (see ► ["Evolution of Communication"](#)).

Embedding of phrases in language (often confusingly termed recursion) is more complicated than either diagram above. Each phrase consists of components with different roles, for instance, nouns and verbs, or more generally objects and attributes. The exact relationship of these two types of components in a phrase is marked either by their sequence or by tags (inflections), and the relationships of phrases are also marked by their sequence or by tags (conjunctions). A more accurate diagram of embedding in language is thus $(A1(B1B2)A2)$, where A and B are phrases and 1 and 2 designate appropriate objects and attributes within each phrase (Corballis 2007). A human receiver associates A1 with A2 and B1 with B2. These associations are either temporal (for a listener) or spatial (for a reader). The cognitive issue is whether or not nonhuman organisms can respond reliably to $(A1-A2)$ regardless of whether these two components are separated in time or space by analogous phrases, such as $(B1B2)$.

Sensations evoking responses by animals are often (perhaps always) composed of multiple elements in particular arrangements. Thus it is not surprising to find that animals can master associations like $(A1-A2)$ regardless of some interruptions. An ability to respond to the associated sensations despite interruption comes

close to object constancy, discussed above. The experiments mentioned above, which show that birds fail to generalize such patterns (Van Heijningen et al. 2009), perhaps miss the point. Object constancy is probably not generalized either; instead each object is learned by family resemblance of its particular features, despite various interruptions, and eventually evokes a unitary response. Furthermore, as discussed above, it is not clear that using language requires parsing of components.

Embedding in language is even more complex, because in this simple case, (B1B2) modifies A1, so that (A1B1B2A2) becomes in effect ((A1(B1B2))A2). The phrase “The cat that the dog attacks hisses” does not merely merge two phrases “The cat hisses” plus “The dog attacks.” Instead the inner phrase changes the meaning of the outer phrase; the conjunction makes the connection. Can some nonhuman animals recognize an association of two signals, each of which associates components from two categories, regardless of whether one signal is interposed between the components of the other signal? Perhaps.

As important as embedding is for human language, the relationship established by an action also seems critical, as in a phrase such as “The dog attacks the cat.” The relationship between the “dog” and “cat” is in part specified by the action “attacks” but also by marks that indicate the relationship of each object to the action. This latter relationship is marked in English primarily by sequence: (A1 B1 A2). In Russian, and many other languages, the relationships are marked by modification of each noun (the case of each noun, either nominative or accusative): (A1n B1 A2a). In Russian, sequence has less salience (and determinatives are usually absent), so this inflected phrase would elicit a similar response in the sequence (A2a A1n B1) or in any other sequence. Can animals recognize a three-component signal in which the components have particular relationships specified either by arrangement in time or space or by at least one modifying (case) component. Despite the complexity, this challenge is nevertheless met by some nonhuman animals (Herman and Richards 1984; Marino et al. 2007).

Language as Criteria for Responses

The forgoing discussion has failed to identify a key to language. It has made little progress in isolating any qualitative requirement for the use of language that nonhuman animals do not already have, in some cases to a considerable degree. Yet it seems clear that no other species engages in communication approaching the complexity of human language. Nor have they achieved the levels of technological competence that language has catalyzed among humans. Before suggesting a solution to this paradox, this section first provides a different way to conceptualize the use of language. Recent thinking about language has usually started from the top, from idealizations by grammarians and linguists (Hauser et al. 2002; Chomsky 2005; Tomasello 2010; Fitch 2017; Seyfarth and Cheney 2017). The following starts from the bottom, from basic neural mechanisms for all communication.

Language consists of clusters of perceptions. Categorizing clusters of perceptions to form components of language is fundamentally the same as categorizing sensations to form primary perceptions. Sensations have inherent variability, as a result of variation introduced by their sources (including human signalers, speakers, writers, or signers), their receivers (including human listeners, readers, or sign readers), and the medium in between. This variability is noise in the perception of signals. All receivers of signals in noise make decisions to associate sensations with responses by means of criteria for response (Wiley 2015, 2017; see ► “[Evolution of Communication](#)”). These criteria associate particular sets of incident sensations with particular sets or levels of responses, either overt or covert, in action or memory. Classification of sensations is thus a result of their associations with responses. Initial perceptions are the first responses to sensations.

The criteria for each decision, like all other features of living organisms, develop in the course of each individual’s life as a result of an interaction between its genetic constitution and its environmental conditions. At any moment these criteria depend on the individual’s current physiological and anatomical state. The association of

sensory input with response thus results from the individual's current state and the impinging sensations.

Classification of sensations is the preliminary stage in the eventual classification of perceptions into the components of language. Initial perceptions are the fundamentally meaningful categories of sensations. At each subsequent stage of categorization, the process of association divides perceptions into progressively more specific perceptions or other responses. At each stage, the criteria for categories might combine definitions and family resemblances, and the criteria might change, with developing familiarity, from sequential or inflectional parsing of relationships among components to immediate unitary detection. The inherent variation in sensations at the root of the process propagates into variation in perceptions at every higher stage. Noise permeates all stages in the processing of language. It requires neural decisions to recognize categories of sensations or perceptions at each stage. The variation and exceptions are as important as the norms.

This perspective of language does not preclude human cognitive criteria that quantitatively exceed those of nonhumans. Yet it has not identified a qualitative cognitive capability that nonhumans entirely lack. Combinations of associations in time and space admit great complexity. Increased complexity no doubt can lead to a "great leap forward." It is a truism that quantitative change can lead to qualitative change. Indeed humans have a nearly inexhaustible impulse to categorize, so any change, no matter how small, can invite categorization as a qualitative change. Yet it is not clear whether or not such a "leap" requires any innovations beyond one small step at a time on the same path. Nevertheless, something extraordinary happened when human language developed. It might not have required any advance in cognition.

From Nonhuman to Human Language

Chimpanzees, bonobos, bottlenose dolphins, grey parrots, and other nonhuman animals have

demonstrated surprising capabilities (Savage-Rumbaugh and Lewin 1994; Marino et al. 2007; Pepperberg 2004). They easily master the use of abstract symbols, reference, displacement, and sequential recombinations. They can both produce and respond appropriately to symbols. They can use symbols to communicate with conspecifics to solve problems. They can to some extent acquire these capabilities from other conspecifics.

Despite some animals' language-like abilities, there is no clear evidence that these abilities are used for communication in natural situations. It is interaction with language-capable humans that reveals the inchoate capabilities for language in apes, parrots, and dolphins. This situation recalls a repeated result of all mathematical models for the evolution of communication. The initiation of communication, of whatever simplicity or complexity, must surmount a hurdle. Rare alleles associated with response to a new signal are unlikely to spread in the absence of individuals producing the signal. Conversely, rare alleles associated with producing a new signal are unlikely to spread in the absence of individuals responding to the signal. As seen in the models for the evolution of communication in noise and for the evolution of traits and preferences by sexual selection, the benefits of signaling depend on responses, and the benefits of responding depend on signals. The frequencies of signals and of responses must reach some threshold before the benefits of signaling and responding begin to spread (see ► ["Evolution of Communication"](#) and ► ["Sexual Selection"](#)).

This conclusion invites application to these language-capable but language-deficient populations. Chimpanzees have evolved enough mental capabilities to provide the advantages of language, yet in natural situations language among chimpanzees is, by all evidence, absent. There could well be advantages for apes to have language to assist in coordinating cooperation within their groups and competition between groups. They appear to have enough of a start in mental competence. Perhaps, so far, neither the frequency of gestures nor responses have reached the necessary threshold. Who knows? Perhaps a

fortunate coincidence, just one small group with by chance a few gesturers and a few responders, a few individuals with just the requisite predispositions, such as Kanzi seemed to have, and overnight a new kind of chimpanzee society based on new possibilities for communication would sprout. Subsequent natural selection would enhance these incipient predispositions for specialized learning.

After that leap forward, natural selection would result in evolution toward optimal signaling and responding. Perhaps it would evolve rapidly, accelerating as expected for sexual selection but also for any frequency-dependent selection of mutualism in communication. The increase in size and complexity of society with the introduction of agriculture might contribute to selection for greater complexity in language. The concurrent invention of writing would almost certainly increase the potential complexity, as a result of the greater storage and review of language. Then there would come printing and eventually the Internet and computers to assist with storage, search, translation, and associations of language. Perhaps even tools and fire might have affected the evolution of language, or, perhaps more likely, language affected them.

It is easy to imagine how increasing competence with language could improve thinking, which is after all internal communication. It presumably would require higher levels of association and memory. In contrast, a proposal that language-like thought might *precede* language for external communication with other individuals seems unlikely. Private language would lack the stability acquired from consilience in the process of communication with other individuals (Wiley 2015). Instead the evolution of language is likely to have promoted the evolution of thinking.

Conclusion

This scenario supposes that the advantages of complex hierarchical societies with some incipient forms of cooperation and monitoring of other individual's social relationships might have favored the initial evolution of advanced mental

capabilities. The advantages of multiplicity and specificity in individual recognition might be enough to promote the evolution of complex associational learning. The requirements for criteria based on complicated family resemblances and for object constancy in challenging conditions might produce enough cognitive complexity. The ultimate form of cooperation, language, would then just need the impetus to get past the impasse of signalers without receivers and receivers without signalers. A boost in frequencies of signals and responses might come with a random perturbation during a bottleneck in population size. After crossing the initial hurdle, natural selection on the predispositions for language could take hold. Perhaps faster than so far imagined, the use of language would flourish.

Synonyms

Erectile disorder; Erectile dysfunction; Female sexual interest/arousal disorder; Hypoactive sexual desire disorder; Impotence; Inhibited sexual desire; Low libido, female sexual arousal disorder; Low sexual desire

Definition

Sexual desire is a motivational state that is characterized by heightened interest in sexual stimuli and a drive to seek, initiate, and/or continue sexual activity. *Sexual arousal* is the bodily and mental sexual response to sexual stimuli during or in anticipation of sexual activity. *Hypoactive sexual desire disorder* (HSDD) is a persistent deficiency or absence of sexual/erotic thoughts and fantasies and desire for sexual activity that induces distress in the subject. *Female sexual arousal disorder* (FSAD) is an inability to attain or maintain sexual arousal during sexual activity and/or to have inadequate genital lubrication-swelling response during arousal and sexual activity, and that induces distress in the subject. *Erectile dysfunction* (ED) is the marked difficulty in obtaining and/or maintaining an erection during sexual activity and/or a marked decrease in penile rigidity.

Introduction

The manifestation of sexual desire and arousal is dependent upon two separate but interacting systems: a sexual excitation system and a sexual inhibition system (dual control model of sexual response; Janssen and Bancroft 1996). These opposing systems are differentially activated based on the presence of internal and external stimuli, internal state, and the expectation of reward and of negative consequences. The net activity determines the presence and strength of sexual desire and arousal and, ultimately, sexual behavior. Sexual stimuli or cues automatically trigger the sexual excitation system, which is necessary but not sufficient for a sexual response. The expression of a sexual response is dependent upon the potency of the erotic stimulus, the internal state (e.g., a satiated or non-satiated state), and other stimuli and/or cognitions signaling the immediate and delayed consequences of sexual responding. A potent sexual stimulus can activate the sexual excitation system (but also a weaker stimulus in an extremely non-satiated state), but if the consequences of sexual responding are perceived as negative, the response is dampened or

prohibited by activation of the sexual inhibition system. This allows adaptive responding and ensures that sexual behavior is less likely to occur when the consequences of such behavior are negative. Imbalance of these systems can lead to sexual dysfunction. Men and women who have a low propensity for sexual excitation or a high propensity for sexual inhibition are more likely to develop sexual dysfunction. However, by definition, these individuals do not yet *have* a sexual dysfunction, as such a diagnosis can only be made when absent/decreased desire and/or arousal induces substantial distress. When someone has a low propensity for sexual excitation, a potent sexual stimulus will have a reduced chance of inducing a sexual response. When someone has a high propensity for sexual inhibition, a sexual stimulus may induce activation of the sexual excitation system, but this activity (and the concomitant sexual response) is then quickly reduced by (continuous) over-activation of their sexual inhibition system. Either way, the net effect is decreased or no sexual desire and decreased or no sexual arousal. A differentiation based on this division has been operationalized for women with sexual desire and arousal problems (Bloemers et al. 2013), but the model likely holds for men with desire problems and psychogenic erectile dysfunction as well. In this model, women with a low propensity for sexual excitation are characterized by their low sensitivity of the brain for sexual stimuli, possibly due to altered function of their androgen system. Women with dysfunctional over-activation of their sexual inhibitory mechanisms are characterized by over-activity of their dorsolateral prefrontal cortex in response to sexual stimuli. The dorsolateral prefrontal cortex mediates inhibitory control of (motivated) behavior. The inhibitory neurotransmitter serotonin plays a key role herein. Unfortunately, it is not readily apparent to which category a patient belongs because the symptoms, low desire and/or low arousal, are the same for both these subgroups. A demarcation formula using both biological as well as psychological variables is needed to determine if a patient is low sensitive or high inhibitory (Tuiten et al. 2018).

Sexual desire and arousal problems often coexist. The sexual excitation and sexual inhibition systems influence both desire and arousal, so either excitatory or inhibitory dysfunction can then also easily impact both desire and arousal simultaneously. However, sexual desire problems can also exist without concomitant sexual arousal problems and vice versa. This separation between low sexual desire and low sexual arousal has been the topic of an ongoing debate ever since the development and launch of the 5th edition of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM5; APA 2013). In this latest DSM edition, the DSM-IV (APA 2000) diagnosis of female hypoactive sexual desire disorder (HSDD) and female sexual arousal disorder (FSAD) are merged into a single diagnosis of female sexual interest/arousal disorder (FSIAD). This merged category has merit, because it is consistent with the premise of the dual control model that dysfunction on the excitatory or inhibitory side can impact both desire and arousal. It contradicts evidence, however, that HSDD and FSAD can exist separately without the other. Although not the intention of this entry to discuss the validity of FSIAD versus HSDD and FSAD, all that is outlined further below applies to both diagnostic categorizations unless otherwise stated.

Sexual Desire Disorders

Hypoactive sexual desire disorder (HSDD) is characterized by a persistent deficiency or absence of sexual/erotic thoughts and fantasies and desire for sexual activity. For a formal diagnosis according to the *Diagnostic and Statistical Manual for Mental Disorders* (4th edition, text revision; DSM-IV TR), the complaints must have persisted for at least 6 months, cause clinically significant distress in the individual, and cannot be attributed to other mental disorders, relationship distress, other significant stressors, a medical condition, or drug use/abuse. The prevalence of HSDD in women is approximately 8–19% (Goldstein et al. 2017), although many studies indicate a higher prevalence. Estimations of

prevalence of HSDD in men also vary greatly, ranging from approximately 3% to 16% (Krakowsky and Grober 2016). Problems in low desire can negatively impact the quality of life (Laumann et al. 1999).

The neural regulation of sexual excitation (and thus desire), even though it is far from being fully elucidated, can be split into several functional domains. Sensitivity to sexual cues reflects the brain's responsiveness to sexual stimuli. This is in part mediated by (among others, androgen functioning in) the amygdalae, which are known for their role in attributing salience to a stimulus, and the mesolimbic dopaminergic pathway that projects dopamine to the nucleus accumbens through the dopaminergic cells of the ventral tegmental area. The mesolimbic system mediates incentive salience and innervates the amygdalae, and functioning of this circuit is therefore key in someone's sensitivity to sexual stimuli. Other areas that play an important role in sexual excitation are, for example, the medial preoptic area, locus coeruleus which contains noradrenergic neurons, and the arcuate nucleus. Sexual inhibition has the more executive role as opposed to the sexual excitation system which is more automatic. The inhibition system "ascertains" if the consequences of the automatically turned on excitation system (i.e., sexual responses) are advantageous. The prefrontal cortex plays an important role in the inhibition of sexual behavior, especially the dorsolateral prefrontal cortex. A key neurotransmitter in this inhibitory control is serotonin. A propensity for increased activation of the sexual inhibition system may be caused by increased serotonergic activity in the prefrontal cortex. Indeed, drugs that augment serotonergic action in the prefrontal cortex (e.g., selective serotonin reuptake inhibitors) often induce severe sexual dysfunction as a side effect (Clayton et al. 2002). Other inhibitory modulators are opioids, endocannabinoids, and oxytocin, which are released following orgasm and play a role in satiation.

The insula and anterior temporal cortices also play an important role in the perception of a sexual response. The insula mediates the perception of physiological response (interoception).

Interoceptive stimuli are reprocessed with increasingly complex information, in a posterior to anterior gradient, accumulating in the anterior insula and forming subjective awareness of the (sexual) response. The anterior temporal cortices integrate this information with visceral-emotional information from multimodal association areas, giving a global (sexual) emotional state.

There are several social/psychological and pharmacological treatment options for HSDD. Psychotherapy and cognitive behavior therapy typically address beliefs, thoughts, emotions, behavior, and relationship communication and interaction that are counterproductive in developing, experiencing, or maintaining sexual desire. For example, patients may learn to “stay in the moment” and not stray in distracting thoughts that typically inhibit the sexual response or unlearn negative thoughts that stem from cultural or religious beliefs. Sensate focus therapy and many other forms of sex therapy emphasize the importance of (sexual) communication in the relationship and employ sensual touching exercises to gradually improve sexual intimacy. To date, there are no approved pharmacological therapies for HSDD for men and only one for women. There are several drugs in different stages of development and several off-label options that have been shown to have some merit. Agents that enhance dopaminergic functioning (e.g., bupropion, cabergoline, ropinirole) may be used. Theoretically, these should increase incentive salience and sexual motivation by mimicking actions of, or facilitating, the mesolimbic dopamine system. Agents that alter serotonergic function, and thereby target inhibitory control, may also be used, like flibanserin, which is the only regulatory approved drug in the USA for HSDD in premenopausal women. Flibanserin is a serotonin 1a receptor agonist and serotonin 2a receptor antagonist with a once-daily dosing regime. It has been shown to decrease serotonin levels in the brain but also increases dopamine and noradrenaline levels. Theoretically this is a sound approach, but the efficacy of the drug in women has been criticized because of the meager difference in its efficacy versus placebo (Jaspers et al. 2016). Bremelanotide, an on-demand melanocortin

receptor agonist administered by injection, has shown promising efficacy in women with HSDD. Two other on-demand drug combination products have also shown promising efficacy in women with HSDD/FSIAD. One is a combination tablet that combines the sublingual administration of testosterone with delayed release of oral sildenafil. This method of administration ensures the overlap of the pharmacodynamic effects of both compounds and is designed specifically for women with HSDD/FSIAD who show lower neural sensitivity for sexual stimuli. The second on-demand combination tablet has been designed for women with HSDD/FSIAD due to dysfunctional over-activation of sexual inhibition. It combines sublingual administration of testosterone with delayed release of buspirone and transiently decreases sexual inhibition. Chronic testosterone therapy is also used off-label in men and women, with mixed results especially in women (Khera 2015).

Sexual Arousal Disorders

Female sexual arousal disorder (FSAD) is characterized by the inability to attain or maintain sexual arousal during sexual activity and/or to have inadequate genital lubrication-swelling response during arousal and sexual activity. It causes marked distress or interpersonal difficulties that cannot be attributed to another mental disorder, relationship distress, other significant stressors, a medical condition, or drug use/abuse. The prevalence of FSAD ranges from 6% to 28% of women, and prevalence is likely tied with increasing age (Giraldi et al. 2013). Erectile dysfunction (ED) is the marked difficulty in obtaining and/or maintaining an erection during sexual activity and/or a marked decrease in penile rigidity. The complaints must have persisted for at least 6 months and cause clinically significant distress in the individual and are not caused by other mental disorders or as the result of relationship distress, other significant stressors, a medical condition, or drug use/abuse. The prevalence of ED is strongly tied to age, with approximately 2% of men in their 40s, rising to 25–30% of men in their

60s who suffer from ED (Boyle 2009). Problems in low sexual arousal/erectile dysfunction can negatively impact the quality of life (Laumann et al. 1999).

For adequate sexual arousal, the central mechanisms described under section, “[Sexual Desire Disorders](#)” also need to be functional. Peripherally, the genital sexual arousal response is largely determined by the engorgement of the genitalia with blood. The mechanism underlying genital engorgement is comparable in men and women because the genitalia share the same embryological origin. Genital engorgement leads to an erection in men and to erection of the clitoral complex in women, which subsequently induces vaginal lubrication. The cavernosal tissue that allows this swelling response consists of many small balloon-like arteries that are lined with smooth muscles. Most of the time, these muscles are constricted through sympathetic innervation so that the arteries themselves remain narrow. Under condition of central sexual stimulation (see above), the parasympathetic division of the autonomic nervous system triggers nitric oxide (NO) release from nerves and endothelium which induces production of cyclic guanosine monophosphate (cGMP). cGMP is a key mechanism in the relaxation of the smooth muscles. When the smooth muscles relax, the corpus cavernosa fills with blood, while at the same time the veins are constricted, limiting the outflow of blood. Factors that interfere with this process interfere with the peripheral sexual response. For example, if a central sexual response is dampened (see section “[Sexual Desire Disorders](#)”) parasympathetic activation will not be triggered, or will be triggered insufficiently, so that the entire process is not set in action. Psychological factors that induce sympathetic activation (e.g., anxiety) can also decrease the genital response through heightened or persistent sympathetic activation that outweighs the parasympathetic innervation. Also, diseases or substances affecting arterial functioning like diabetes mellitus and smoking can negatively affect genital arousal. Moreover, the hormonal milieu in men and women are also important for a functional genital response. In men and women,

testosterone is needed for the production of NO, and estrogens thicken and moisten the vaginal epithelium in women. Decreasing estrogen levels, for example, during and following the menopausal transition, or decreasing androgen levels in aging men and women can result in impaired genital arousal (Dennerstein et al. 2002; Araujo and Wittert 2011).

Arousal disorders can be often be treated like desire disorders because of the common etiology it shares with desire disorders. When arousal problems stem from a noncentral cause, peripherally acting drugs may also be beneficial. ED is often successfully treated with phosphodiesterase 5 (PDE5) inhibitors (e.g., sildenafil, vardenafil, tadalafil). PDE5 breaks down cGMP, so by inhibiting this inhibitory factor by the use of a PDE5 inhibitor, genital engorgement is facilitated. PDE5 inhibitors are effective in some women with FSAD, but it is not approved for this indication and thus remains to be prescribed off-label. Hormone replacement therapy (e.g., testosterone supplementation or estrogen replacement therapy) can also help with arousal problems in people with lower levels of the respective hormone.

Conclusion

Sexual desire and arousal disorders have a heterogeneous etiology, and much is still unclear. Truly effective psychotherapeutic and pharmacotherapeutic options are still lacking but very much needed as these disorders can have a detrimental impact on quality of life.

Desire to Be Included Among Desirable Women

Steven Arnocky

Department of Psychology, Faculty of Arts and Sciences, Nipissing University, North Bay, ON, Canada

Synonyms

Appearance enhancement effort; Attractiveness effort; Epigamic display; Intersexual selection

Definition

Women's desire to be considered among “desirable” women involves motivation and effort toward displaying attributes that enhance their desirability as either a mating or social partner.

Introduction

Men, more than women, prefer physically attractive and sexually faithful mates. Women and girls who are high on these desired traits might also be more popular within their same-sex peer networks. Accordingly, women, more than men, are

motivated to display and accentuate these mate-value and peer-valued characteristics, which are, in part, signals of reproductively and socially relevant information. Social-cognitive mechanisms such as social comparison, as well as emotions such as envy, appear to underlie some behaviors associated with women's desire to be considered among desirable women.

Across diverse human cultures, men's and women's mate preferences have been shown to diverge in reproductively important ways. One of the most consistent sex differences is men's greater expressed preference for physically attractive partners. For instance, Buss (1989) found that in each of 37 cultures studied, men more than women desired partners who were youthful and physically attractive. Moreover, men are remarkably consistent in the specific features that they find attractive in a mate. These features typically include lustrous hair, clear skin, full breasts, feminine and symmetrical facial features, and a low waist-to-hip ratio (i.e., an hourglass figure) (Buss 1989; see Arnocky et al. 2014 for review). A growing body of evidence suggests that such physical features may have evolved, in part, as relatively honest cues to reproductively important aspects of women's phenotypic condition, including youth (i.e., being of reproductive age), underlying health, and/or fertility (Arnocky et al. 2014). Ancestral men who happened to be attracted to these features would therefore have out-reproduced those who did not share their preferences (Arnocky et al. 2014). To the extent that mate preferences for condition-linked physical features are heritable, such preferences would proliferate and become prevalent in the population.

Another mate preference along which men and women sometimes differ is the desire for fidelity in a long-term partner. In the Buss (1989) study, 23 of 37 cultures expressed a sex difference whereby men more than women preferred a chaste partner. As with physical attractiveness, a mating partner's chastity also bears more heavily on men's, relative to women's, reproductive success. Due to concealed ovulation and the internal fertilization process of human reproduction, men can

never be certain of their paternity. Indeed, genetic cuckoldry continues in contemporary human society, although estimates of its frequency vary considerably. Accordingly, ancestral men who valued fidelity in a partner may have been less susceptible to cuckoldry (i.e., unwittingly investing parental effort toward offspring that are not genetically one's own) and thus may have been more reproductively successful relative to men who did not value chastity.

Given men's preferences for youthful, attractive, and faithful partners, it is intuitive that intersexual selection (i.e., mate choice) would favor women who best display these features. For example, physically attractive women are more likely to be asked out on dates (Walster et al. 1966), are more likely to be approached by men at social gatherings such as parties (Prestia et al. 2002), are more successful at poaching mates (i.e., stealing a partner from an already established mating relationship) (Sunderani et al. 2013), become sexually active earlier in life (i.e., have a longer period of reproductive potential), and have more long-term dating partners compared to less physically attractive women (Rhodes et al. 2005). Not surprisingly, physically attractive women are thus able to express greater choosiness for who they mate with. Similarly, women who are perceived as chaste (i.e., easy to mate with within the relationship, but hard for other men to mate with) are more desirable as dating partners than either uniformly hard or uniformly easy-to-mate-with women (Walster et al. 1973). The mating advantage afforded to women who best typify men's mate preferences serves as a powerful force in directing women's social-cognitive functioning, emotions, and behavioral efforts toward being considered desirable as a mate.

Evidence of Women's Desire to be Physically Attractive

Whereas features of physical attractiveness may have evolved as honest cues to mate value, there exists abundant historical and cross-cultural

evidence that women have long attempted to augment their physical appearances in ways that coincide with men's mate preferences. To a degree, women can influence the honesty of the cues associated with phenotypic features and in doing so benefit their mating success. When women are asked how they attract mates (i.e., successful intersexual selection), they often report attempting to explicitly enhance their physical appearances, such as through wearing makeup, wearing stylish clothes, keeping clean and well-groomed, as well as using skin-tanning products and applying nail polish (see Arnocky and Vaillancourt 2014 for review). Western women spend nearly ten times more money than men on products meant to enhance their physical appearances and are twice as likely to work on their appearance for more than 1 h per day (see Arnocky and Vaillancourt 2014). Three lines of evidence stemming from (1) explicit surveying and manipulation of mating motives and (2) ovulatory shifts in fertility, and (3) effects of differential mate availability, converge to suggest that women's use of appearance-enhancement behaviors are broadly linked to their mating motives.

First, mating motives have been shown to predict a range of appearance-enhancement behaviors among women. Hill et al. (2012) showed that although spending on most products decreases during an economic recession (or when experimentally primed with recession cues), women nevertheless increase spending on appearance-enhancing products (termed "the lipstick effect"). Moreover, the researchers found that women's reported preference for attracting mates with resources mediated this effect. Further experimental evidence suggests that women's appearance-enhancement motives are often linked to a desire to be viewed as attractive to members of the opposite sex. For instance, Hill and Durante (2011) found that single women who were primed with mating motives (versus control) were more interested in skin tanning and taking risky diet pills, highlighting the disconcerting fact that women sometimes engage in appearance-enhancement efforts that are risky to their health as a function of their mating motives. For example, eating disorders are significantly more

common among those who are most likely involved in intersexual selection and intrasexual competition. Heterosexual women in their prime reproductive years, compared to men, older women who are outside of reproductive age, and homosexual women, are more likely to exhibit eating disorder symptoms (e.g., Abed et al. 2012). Eating disorder behavior has also recently been shown to be predicted by a fast life history (characterized by greater reproductive and mating effort) among college-age women (Abed et al. 2012). It is important to note that physical appearance enhancement is not only a function of women's initial mate-attraction efforts but is also reported by women, more than men, as an effective mate-retention tactic (see Arnocky and Vaillancourt 2014 for review).

Second, shifts in appearance-related efforts occur throughout the menstrual cycle. When women are in the fertile phase of the cycle, they are more likely to wear more revealing clothing; an effect that is enhanced among those women higher in sociosexuality (Durante et al. 2008). Women also report an increase in self-perceived attractiveness and feelings of sexiness during ovulation (see Durante et al. 2008 for review). During ovulation, women have been shown to increase their behaviors associated with intersexual selection (i.e., outcompeting rivals for the favor of desired males). Haselton and colleagues (2007) showed that partnered women who were photographed at high and low fertility points in the menstrual cycle were rated as "trying to look more attractive" during high fertility phases, and the closer women were to ovulation when photographed, the more frequently their fertile photograph was classified as attempting to enhance their appearance. This hormonally regulated effect appears to be driven by a desire to outdo attractive rival women. For instance, women have been shown to choose products that enhance their physical appearance (e.g., "sexy" rather than more conservative clothing) more frequently during ovulation. Importantly, this ovulatory shift in behavior occurs when women view photos of attractive intrasexual rivals, but not after viewing unattractive rivals, attractive, or unattractive men (Durante et al. 2011).

Third, where men are scarce, women have been found to wear more revealing clothing, relative to where men are abundant (Barber 1999), suggesting that increased ecological pressure on securing a mate may increase women's efforts in the realm of intersexual selection.

Social-Cognitive and Emotional Influences on Women's Appearance Enhancement

Competing for mates depends not only on individuals' own attributes but also on the attributes of intrasexual competitors (Arnocky et al. 2016). From this perspective, women who are best able to compare their mate-value characteristics to those of their nearest rivals would be better able to determine the requisite level of investment in ornamentation necessary to outcompete rivals for desired mating opportunities, without over-investing. Moreover, unfavorable social comparisons on dimensions of physical attractiveness may result in an emotional response of envy (i.e., the unpleasant experience of hostility, inferiority, and resentment toward those who possess something desirable), which may in turn motivate appropriate compensatory behavior(s) aimed at augmenting that characteristic. To test this hypothesis, Arnocky et al. (2016) randomly assigned women to one of two conditions: an appearance-based social comparison condition, where women viewed magazine ads containing female models and were asked to compare their appearance to the target, and a control condition where women viewed different magazine ads from the same companies, but which did not feature a female model prominently in the ad. Following the priming condition, women reported on their state feelings of envy, followed by measures assessing a host of appearance-enhancement motives. Their results indicated that women who were primed to make physical appearance comparisons to models expressed more envy compared to controls, and the envy in turn predicted more favorable attitudes toward having cosmetic surgery, more

intended use of facial cosmetics, and more willingness to use a risky diet pill. These findings suggest that women's mating-relevant ornamentation efforts are sensitive to environmental inputs in terms of the relative quality of their same-sex conspecifics, as well as the emotional outcomes of such comparisons.

Evidence of Women's Desire to be Perceived as Chaste

When men invest in offspring, women behave in ways that will ensure or reinforce greater paternity confidence. Following births, hospital room videotapes indicate that mothers (and other relatives) allege paternal resemblance of the newborn much more often than maternal resemblance, supporting the hypothesis that women behave in ways to promote paternity confidence (i.e., enforce their chastity) to male partners. Women also generally report having fewer sex partners than men, and confusion has existed in the literature as to whether this is a function of male overreporting, female underreporting, or perhaps both. This is complicated by the fact that as many as 60 % of undergraduate men and women report having acted deceptively with their representation of their number of previous sexual partners (Horan 2015). One recent study sought to address this differential disclosure by having half of the sample's participants complete a questionnaire on sexual and social behaviors while connected to a lie detector (which was, unbeknown to the participants, nonfunctional). Results showed a significant gender by lie detector interaction, whereby women (more than men) were more likely to report not having engaged in sexual intercourse when disconnected from a lie detector compared to women who were connected to the lie detector. Women in the lie detector condition reported having more lifetime sex partners than women in the no lie detector condition. Importantly, self-reporting of other types of male or female-typical behaviors did not vary as a function of being attached to a lie detector (Fisher 2013). This suggests that women may underestimate when disclosing information about their sexuality, perhaps

as a mode of preserving a reputation of sexual restrictedness.

Taken together, evidence suggests that women attempt to augment their physical appearances and sexual reputations in a manner that conforms to the mate-preferences of men. Yet beyond intersexual selection, individual differences in these characteristics can also influence desirability within the broader social network, with mating-relevant implications.

Attractiveness, Sexual Behavior, and Social Status and Affiliation

Both physical attractiveness and sexual reputation have been linked to girls' and women's social statuses, friendships, and affiliations. Ancestrally, social acceptance would have played a vital role in acquiring food, shelter, protection, and mating opportunities (Brown et al. 2009). Moreover, females' relative to male's same-sex affiliations are characterized by greater emotional and informational support (Hall 2011). Women report that their same-sex friends provide mating advice and assist in mate-acquisition (Bleske and Buss 2000). Brown et al. (2009) argued that in achieving social acceptance, individuals are able thus to focus more of their attention and efforts toward mating. Across two studies, the authors showed that cues to social acceptance (e.g., being included in a ball-tossing game) increased participants' interest in mating with targets whose faces were presented on a screen.

The influence of physical attractiveness upon the lives of women begins at an early age, including having effects on social affiliation. For instance, Krantz (1987) found that for girls, but not boys, those rated as being most physically attractive prior to beginning kindergarten were more likely to be considered popular in school. In adolescence, longitudinal research has shown that physical attractiveness correlates with peer-rated popularity within the social group (Arnocky and Vaillancourt 2012). Even socially rejected girls are less likely to be overtly victimized by their peers if they happen to be physically attractive (Knack et al. 2012). Among young-adult

college students, attractive individuals are perceived to have more socially desirable personalities. Attractive women may be ascribed with higher social status and exert more social influence compared to less attractive women (see Arnocky et al. 2014). Moreover, attractive individuals (both men and women) are more likely to receive social help. Benson et al. (1976) left a completed graduate school application form, a photograph of the applicant, and an addressed, stamped envelope in a telephone booth. The picture varied by attractiveness (high and low) and ethnicity (black and white). The applicant's physical attractiveness predicted whether or not the application was delivered. However, some research suggests that the importance of physical attractiveness to friendships and overall social acceptance may be primarily relevant in cultures where individual choice in the establishment and maintenance of social relations is the norm (Anderson et al. 2008). Nevertheless, there is some research to suggest that females explicitly understand the importance of physical attractiveness to their social status: When asked to describe popularity, girls more than boys identified being attractive as an important component of being popular (Closson 2009).

Sexual behavior has also been linked to girls' popularity and friendships. Considering females' significant obligatory parental investment, female sexuality is a scarcer resource than males'. Baumeister and Vohs (2004) have argued that women would thus benefit from regulating the value of their sexuality by artificially restricting the supply via placing "pressure on each other to exercise sexual restraint" (Baumeister and Vohs 2004, p. 344). Such pressure may be exerted via social affiliation, whereby less sexually restricted females may become socially isolated and/or chastised by other females. Because of this, it has been argued that adolescent girls experience and express firm social norms that sexual behavior should not occur outside of dating relations (see Arnocky and Vaillancourt 2012 for review). Prinstein et al. (2003) found that adolescent sexual activity correlated positively with reputation-based popularity, but not likeability among peers. Moreover, increasing number of sex

partners correlated with lower popularity. Kreager and Staff (2009) found that girls with many sex partners reported having fewer friends – a relationship that did not exist among male participants. Moreover, women who are low in sociosexuality (i.e., have a more monogamous orientation toward sexual activity) are more sensitive to the popularity impacts of various dating risk situations (Rinehart 2012). Recently, Vrangalova et al. (2013) surveyed 750 undergraduates about their sexual behaviors and attitudes. Then, participants read a short description of a hypothetical person of the same sex who had either 2 or 20 past sex partners. Participants then rated this hypothetical persona as a potential friend. Results showed that women, regardless of their own sexual histories, overwhelmingly preferred the potential friend with fewer past sex partners. Given the adaptive significance of social acceptance, women who exhibit characteristics that are associated with receiving social acceptance, friendship, and status are likely advantaged in a variety of reproductively relevant domains.

Conclusion

Over human evolutionary history, the establishment and maintenance of long-standing peer and mating relationships would have been impactful upon women's reproductive success. Yet not all women are desired equally for these important relationships – and some women exhibit morphological and behavioral characteristics that improve their success in domains of interpersonal desirability. In considering two such characteristics, physical attractiveness and sexual reputation, both of which impact interpersonal attraction and interaction, research suggests that women who typify these and other important mate-value and/or peer-valued characteristics are often more desirable as romantic partners and same-sex friends. Unsurprisingly, women, more than men, express psychological and behavioral tendencies toward augmenting and displaying these characteristics, which may benefit their success in intersexual sexual selection and social relations.

Detecting Infidelity

Nicholas J. Moore and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Infidelity refers to a violation of sexual or emotional exclusivity within a pair-bond. Emotional infidelity is when a person allocates their time, love, and attention to someone other than their significant other, whereas sexual infidelity is when a person engages in sexual activity with someone other than their significant other (Shackelford and Buss 1997).

Infidelity is a universal behavior, occurring in all known cultures and times. In the United States, marital infidelity estimates vary from 26% to 70% for women and 33% to 75% for men (reviewed in Shackelford and Buss 1997). Though infidelity may have reproductive benefits (e.g., increase men's reproductive success by increasing the number of mateships), infidelity is associated with various negative outcomes. Women's sexual infidelity is costly to men due to cuckoldry (i.e., raising non-genetically related offspring) or possible loss of a mating partner to a rival, whereas men's emotional infidelity is costly to women due

to loss of parental investment (i.e., time and resources that are redirected to a rival). Infidelity and jealousy are also implicated in many cases of intimate partner violence. Due to the steep costs of infidelity, the ability to detect such acts or risks of such acts may have evolved.

Both men and women appear to be sensitive to cues of infidelity. Men more often recall cues signaling their mates' sexual infidelity whereas women more often recall cues regarding emotional infidelity (Schützwohl and Koch 2004). Shackelford and Buss (1997) identified 170 cues to emotional and sexual infidelity that loaded onto 14 factors. These factors were: (1) angry, critical, argumentative of partner; (2) sexual infidelity revealed; (3) changes in normal routine and sexual behavior with partner; (4) apathetic toward partner; (5) increased sexual interest/exaggerated affection toward partner; (6) sexual disinterest/boredom with partner; (7) relationship dissatisfaction; (8) passive rejection of partner; (9) reluctance to discuss a certain person; (10) reluctance to spend time with partner; (11) increased reference to and time spent with another person; (12) acting guilty, anxious toward partner; (13) physical signs of sexual infidelity; (14) emotional disengagement from partner.

Shackelford and Buss identified some interesting patterns with these cues to infidelity. Participants rated some of these factors as more diagnostic of sexual infidelity, such as sexual boredom, whereas other factors were rated as more diagnostic of emotional infidelity, such as relationship dissatisfaction. These cues are more likely to be considered a cue to infidelity when applying that cue to members of the opposite sex, suggesting the presence of a cognitive bias to perceive acts as signs of infidelity when it is performed by members of the opposite sex.

These factors have been used in other studies to test hypotheses about the effects of infidelity on intimate partner conflict. For example, Camilleri and Quinsey (2009) found that these cues were associated with self-reported propensity for intimate partner sexual coercion. More recent work has found that women are generally more sensitive to partner infidelity, are faster and more accurate in

detecting infidelity, and focus their attention on the rival, whereas men focus more on the intent of their partner (Ein-Dor et al. 2015). Other researchers are addressing how people process cues to infidelity (see Schützwohl 2004, 2005).

Definition

Series of self-constructive and transformative processes that lead to new, eventually more complex states of organismal organization.

Introduction

In the first pages of *The Strategy of the Genes*, Conrad H. Waddington wrote that “the main respect in which the biological picture is more complex than the physical one, is the way in which time is involved in it” (Waddington 1957,

p. 5). While an image of continuous flux is congenial with both ancient and present-day conceptions of the physical, the way in which change, the most distinctive seal of time, enters into the picture when one approaches the organic certainly underlines the breach which exists between the two realms. According to Waddington, this difference becomes even more noticeable when one considers that three different time-scales appear to be relevant when considering the latter realm. At one extreme, one finds (1) the minute, the daily time-scale of metabolism and function; at the other extreme, (2) the geological time-scale of evolution; and in the middle, (3) the individual-life encompassed time-scale of development (Waddington 1957, pp. 5–8). This intermediate developmental time-scale raises some controversial issues which are specific to the natural sciences (Robert 2004, Chap. 1), including their psychological ramifications (Michel and Moore 1995). These questions have mostly to do with the boundaries of the developmental perspective with the other two time-scales, but also with its scope within the whole life-cycle of an organism and with the delimitation of the entity, to which particular development processes must be properly ascribed (Minelli and Pradeu 2014).

Development: The main puzzles

For a long time, probably extending from Aristotle (384–322 BC) to the late nineteenth century, the study of development was basically equivalent to the study of the embryo (Amundson 2005). The entailment thus existed that development, as a matter of scientific interest, reached a somehow meaningful upper limit at the moment of birth. From that point on, the life of an organism entered the realm of physiological research. Such a viewpoint was clearly too closely centered around complex animals and delimited by the certainly relevant, but, ultimately, arbitrary milestone of their life-cycle. The alternative, which gained rapid acceptance (Burian and Thieffry 2000), widened the research scope of developmental studies to the point where organisms become endowed with their own capacity for generating new,

descendant organisms. Such an alternative was not, however, without shortcomings. To start with, it appears to equate “fecundity” and “maturity,” which is by no means a straightforward equation at all. Moreover, it appears to entail an all-or-nothing view of development, according to which the different aspects of the entire mosaic-like developmental process (Schlosser and Wagner 2004) point to the same, synchronous point of termination, where development comes to an end and the adult (reproductive) life of the organism starts.

Irrespective of the point of termination issue, traditional views of development like the ones thus far commented on shared some other problematic stances. For example, they all took for granted that there is a certain “something” that develops but never clarified sufficiently the ontic issue of what exactly that something is. The very meaning of “development” (lit. “un-wrap,” or “un-fold”) appears to entail a preexistent entity, which is modified throughout, rather than brought into existence by, a process of transformations. In any event, the scientific concept of “development” has historically swung between these extremes, routinely referred to as “preformationism” and “epigenesis” (Maienschein 2017) and, indeed, the debate is far from having been satisfactorily resolved.

Historically, research into developmental processes have mostly been conducted from a mechanism-oriented philosophical perspective (Love 2015), nowadays updated as a molecular-computational paradigm (Davidson 1990). This paradigm tends to privilege the internal milieu of the organism as a self-sufficient receptacle of constructive materials and guidelines for development, correspondingly downgrading the environmental contribution to a merely enabling role, which may certainly lead to disruptive effects if not present, but which appears to add nothing in terms of the specificity of the pathways or the intermediary and steady forms. In most cases, however, no clear criteria are offered supporting the ensuing hierarchy (Oyama 2000). Moreover, there exist (nonmarginal) cases in which the environment provides crucial determinants to nontrivial traits (e.g., sex determination

by temperature in fishes, amphibians, and reptiles; Gilbert and Epel 2015, pp. 48–50), or in which environmental and organism-internal products may interchangeably contribute to the attainment of identical phenotypic outcomes (e.g., wing dimorphism in beetles either by a Mendelian-single locus or temperature and food supply; West-Eberhard 2003, pp. 119–121).

Considering these and other similarly powerful arguments, issues of causality, agency, and ontology regarding development have undergone dramatic changes in recent decades. The following, mutually intercrossing points are aimed at offering a more nuanced account of these problematic issues and a necessarily schematic but hopefully informative enough image of an emergent and increasingly supported concept of development in the life sciences, in general, and in psychology, in particular.

1. Temporal Delimitation

Maturity, or adulthood, is customarily thought of as the segment of a life cycle in which a more or less steady form is attained by an organism. According to one interpretation of this viewpoint, maturity is reached when the different organ systems that compose a particular organism have all attained such a plateau phase, relative to prior stages. According to another, alternative interpretation, parallel, but different, developmental cycles are to be considered regarding a single organism, each with a different point of termination. Both interpretations are, however, somewhat problematic, in that steadiness is an extremely relative category. No single organic system ever attains anything like absolute steadiness. While alive, organisms are ever-changing entities, despite differences in the rate of observed change at different moments of their life cycles. Even maturity is a rather relative term, if only because what counts as a juvenile structure in one organism, may count as a mature structure in another similar one (e.g., the external gills and caudal fin of salamander larvae are features typical of mature axolotls; Alberch and Alberch 1981).

The issue appears to be one that cannot be solved but positing some kind of “clock model,”

like the one famously suggested by Stephen J. Gould (1977, pp. 246–262). Such models crucially rely on standardizing a certain stage as a reference point, which may prove an excellent strategy for comparative and evolutionary concerns, but merely an artifact from the point of view of development itself. These kinds of considerations have led some to conclude that even if one decides to keep alive the “segment” metaphor, development must be conceived of as “open-ended” (Minelli 2011). According to a more extreme interpretation, the concept of “development” and the concept of “life” ultimately conflate into one, without much (if any) explanatory loss (Minelli 2003). Conrad Waddington was clearly aware of all of this and he concluded that “to speak of the adult condition as a steady state is to some extent an oversimplification, since developmental change continues at a slow rate throughout adult life, leading eventually to senescence” (Waddington 1957, p. 33).

As for the particular case of psychology, a strong bias has existed towards a “point of termination” view on the development of psychological functions, which kept apart development (or ontogeny) proper, responsible for a basic set of natural cognitive functions, and later processes of cultural development that grow on top of the former (Vygotsky 1978). According to Jean Piaget, for example, cognitive development proper climaxes with the “formal operational stage,” only followed afterwards by lifelong knowledge accumulation or “intellectual development” (Piaget 1962). Thus, both the Vygotskian and the Piagetian traditions appear to agree in endorsing a view of psychological development as a natural process that both precedes and guarantees the acquisition of the cognitive contributions of society and culture by qualitatively different means. Within these classical perspectives, culture is somehow envisioned as an outer, late and increasingly dominant layer of cognitive development, giving grounds to a view where the biology/culture divide appears to assume a limiting role similar to the juvenile/adult distinction.

The biology/culture divide, however, is one viewed with suspicion by current psychobiological approaches (Michel and Moore 1995). It is

ultimately one particular aspect of the strong organism/environment divide, which is also increasingly being contested as supporting a bona fide biological boundary (Gilbert and Epel 2015; Oyama 2000; Sultan 2015). Organic systems incorporate structures that protect them from aggressions or help them to acquire a certain advantageous form, but the “limit” category does not appear to be plausible in biological terms. Organisms are more porous than that. The same applies when one moves to the life-cycle perspective, including the mental life and its specificities. Thus, Minelli’s tenet regarding the “open-ended” character of development appear to be a reasonable conclusion (Balari and Lorenzo 2015). The position entails the conflation of the developmental and the physiological perspectives, including developmental psychology and what some authors have named “cognitive physiology” (Anderson and Lightfoot 2002).

2. Spatial Delimitation

In parallel to the conception that a well-delimited segment of life is accomplished when an organism reaches adulthood, one strongly entrenched position conceives such a segment as the dynamic manifestation of constructive and directive resources internal to the organism. Such an internalist conception does not deny, of course, that the environment makes crucial contributions that help or strengthen development (nutrients, light, gravity, etc.), but it considers them of secondary importance, in that they are not seen as determinants of the attained forms. The idea usually adopts the preformationist stance that everything that is of primary importance for the timely accomplishment of adult designs is a priori given in the genome, as a plan or a program that is simply waiting to be read by extra-genomic intermediaries, both organism-internal and environmental (Mayr 1982). Alternatively, internalism adopts an epigeneticist standpoint, namely one that contends that development is not exactly preformed or planned, but unfolds as the organic conditions are created along the way. Nevertheless, each new stage is determined by the preceding one, so in the end the adult form is

determined by the materials already given at the very start of the process (see Gottlieb 1992, for distinctions within the epigeneticist camp). Both the preformationist approach and the deterministic-epigenetic one share a strong bias towards viewing the organism as the receptacle of the determinants of forms and, as such, as an entity to be set apart from the environment.

This kind of strong, dualistic divide between the inner and the outer (organism/environment, biology/culture, nature/nurture) has notably receded in recent decades (Moore 2001). On the one hand, there seem to be no strong reasons for ascribing to the genome a more central causal profile than to other concurring factors (extra-genomic imprints, RNA sequences, hormones, already attained tissular geometries, etc.), in the absence of which genes are “among the most impotent and useless material imaginable” (West-Eberhard 2003, p. 93). On the other hand, factors of external provenance (nutrients, symbionts, etc.) and dynamics held through the apparently isolating membranes and sensorial systems of an organism (the impact of temperature, of the size of the population, etc.), prove to be crucial for the attainment of forms to no lesser an extent than other factors and dynamics, with the result that ranking the former as secondary relatively to the latter loses any clear motivation (Oyama 2000).

In agreement with the preceding observations, a view on development has emerged based on a plethora of heterogeneous, partially overlapping, complementary or redundant factors, capable of generating, in the absence of any kind of central controller, the material conditions for the timely achievement of successively new states of organismal organization (Griffiths and Hochman 2015). An entailment of this position is that if an underlying developmental system is an inherent property of the organism as an individual entity, and if developmental systems spread out the environment, then the organism itself is not as clearly delimited by, for example, its skin as commonly thought. An interesting derivation of the resulting view leads us back to the preceding point (1), for it is well-known that factors crucial for the successful accomplishment of a certain developmental pathway are of maternal provenance, in the form

of preformed membranous structures, olfactory signals, bacteria, etc. Thus, the entailment also appears to follow that a clear-cut delimitation between developmentally well-defined identities in the temporal axis is not as straightforward as normally assumed (Minelli 2003). In this sense, inasmuch as successive life-cycles appear to overlap, rather than showing clear-cut limits, the boundary between the time-scales of ontogeny and phylogeny appears to become an extremely fuzzy one.

The impact of the previous ideas on the particular area of psychological development is especially clear. Going back to the biology/culture issue, sociocultural stimuli are not just the subject matter of a merely cumulative process of acquisition, as they also act as factors that actively contribute to the growth of neural tissue and structures. The mind of an organism embedded within a more or less rich cultural environment thus becomes a sort of developmental hybrid (Griesemer 2014), an idea that applies equally to humans and nonhuman species, as behavioral patterns transmitted by traditional inheritance are much more widespread than previously thought (Avital and Jablonka 2008).

3. Agency and Causality

The emergent views on development thus far commented on also have an impact on complex metaphysical issues, such as those regarding agency and causality. On the one hand, the kind of pluralism and causal democracy that is increasingly being privileged introduces a rupture with a long-held tradition, according to which development is the quintessence of a directive, goal-oriented or teleological process. However, the strong factorization and the lack of a central controlling instance that are favored by the “developmental system” concept run against such an entrenched teleological tradition. Alternatively, a view is favored according to which developmental processes are contingent, yet reliable and predictable (Gottlieb 2007). Development depends upon many different factors of diverse provenance and, correspondingly, exposed to many potentially perturbing fronts. The directedness of

development, however, is more in the eye of the beholder than an inherent quality of the processes. In other words (with obvious Kantian echoes), development works “as if” it were a goal-oriented process, but it is not.

What will prove to be ultimately responsible for such intuition is one of the central explananda for developmental studies. Current theoretical models increasingly rely on certain organizational properties of systems of development as the key to satisfactorily answering the question. On the one hand, the evolutionary process may be deemed responsible for recruiting factors and creating the most efficacious closeness relations between them; on the other hand, by recruiting mutually reinforcing and partially overlapping and redundant factors, a quality customarily referred to as “robustness,” systems may protect themselves against common perturbations or unexpected failures (Bateson and Gluckman 2011). Such an interplay of historical and systemic properties appears to be the most promissory arena where the mysteries of development can be expected to receive new and more satisfactory answers.

Conclusion

Development is at the center of any possible understanding of what being a piece of living matter means. It is a crossroads of sorts of concepts like organism, individuality, design, environment, plasticity, variation, evolution, purposiveness, robustness, and so on, which are to be currently understood as the key component pieces of the conceptual puzzle of life. While no consensual perspective exists regarding all these issues yet, an emerging and particularly promising one envisions them as leading to a view of development as a nondeterministic, yet robust kind of process, which in the absence of any kind of prefixed goal and central controlling unit replicates the properties of teleological, orchestrated constructive processes, similar to those leading to man-made technological contrivances.

Development is, in all likelihood, life itself and indistinguishable from evolution.
